is often started at 5 µg/kg/min and increased rapidly (5 µg/kg/min every 2 or 3 minutes) to a maximum of 20 µg/kg/min until the target blood pressure is reached. If vasopressor effects are inadequate at these infusion rates, a norepinephrine infusion is begun.

Dobutamine, which is structurally derived from isoproterenol, is a racemic mixture of two synthetic stereoisomers. In combination, the stereoisomers increase myocardial contractility through alpha and beta-1 cardiac adrenoceptors.^{421,422} Weak arteriolar vasodilatory effects are mediated through the dominance of beta-2 adrenoceptor-mediated vascular relaxation over alpha-adrenoceptor-mediated vasoconstriction in the arterial circulation. Evidence suggesting that dobutamine induces vasoconstriction in the systemic venous bed (resulting in increased mean circulatory pressure and the augmentation of venous return/cardiac output) implies that alpha-adrenoceptor-mediated effects may be dominant in small capacitance vessels.^{167,421,422}

Although its hemodynamic effects are otherwise similar to isoproterenol, dobutamine has been reputed to exert minimal chronotropic effects.^{422,423} This attribute has been questioned⁴²⁴ and may have been based on the selection of congestive heart failure patients with beta-adrenoceptor down-regulation and other potential alterations of adrenoceptor signal transduction.^{423,425} Dobutamine's powerful inotropic effect is due to a combination of its direct effect on myocardial contractility, its afterload reducing effect, and alpha-adrenoceptor-mediated venoconstriction.^{422,423} In contrast to dopamine, it causes a reduction in filling pressures and a greater increase in cardiac output at equivalent doses.^{426,427} In addition, although it increases myocardial oxygen demand (like dopamine), myocardial perfusion is also augmented (in contrast to dopamine⁴²⁸). The most well-accepted use of dobutamine in circulatory shock relates to cardiac etiologies.^{422,423} Once blood pressure is corrected, dobutamine may be used to increase cardiac performance and decrease elevated ventricular filling pressures associated with cardiogenic pulmonary edema. In this setting dobutamine may in fact increase blood pressure. Alternately, if myocardial damage is extensive, vasodilatory properties may dominate, resulting in hypotension. Dobutamine may also be of use in obstructive shock pending definitive intervention and can be used to augment low CI occasionally seen in fluid-resuscitated septic shock. Our own experience suggests that maintenance of a PAOP of at least 15 mmHg is required during dobutamine infusion in order to avoid hypotension in patients with septic shock. Its use for augmenting oxygen delivery in septic shock has been substantially abandoned.^{429,430}

Epinephrine is occasionally used when other inotrope/vasopressors have failed to support blood pressure or cardiac output in circulatory shock. It is the first-line agent for management of anaphylactic shock. In addition, it is used to support myocardial contractility postcardiopulmonary bypass.⁴³¹ Epinephrine stimulation of alpha, beta-1, and beta-2 receptors results in increases of myocardial contractility that are more pronounced than with any other inotrope. Nanogram/kg/min infusion rates result in significant increases in cardiac output.⁴³¹ Epinephrine is also frequently used in septic shock refractory to other inotropes/vasopressors. Effects attributable to impaired myocardial

perfusion (chest pain, arrhythmias, ST depression) in patients with known coronary artery disease are usually limited to patients receiving more than 120 ng/kg/min.⁴³² Although the usual infusion rate is 1 to 8 µg/min, higher rates can be used with the potential for increasing toxicity.

Milrinone, a bipyridine phosphodiesterase inhibitor, increases intracellular concentrations of cyclic AMP by blocking cyclic AMP breakdown.⁴¹¹ Although some controversy has existed regarding the relative contributions of increased myocardial contractility and decreased vascular tone with respect to the apparent inotropic properties of phosphodiesterase inhibitors, data confirm the presence of substantial increases of myocardial contractility⁴³³; these agents also produce substantial vasodilatation. The most accepted use for milrinone in the intensive care unit is in the management of congestive heart failure, cardiogenic shock, and postcardiopulmonary bypass myocardial dysfunction.⁴¹¹ Experimental animal studies suggest phosphodiesterase inhibitors may exert beneficial hemodynamic effects in sepsis by augmenting cardiac output and increasing oxygen delivery without increasing consumption.⁴³⁴ Occasional clinical reports suggest a potential management role in catecholamine-refractory septic shock.⁴³⁵

Phenylephrine is a synthetic catecholamine that is unique in its almost pure alpha-adrenergic agonist effects. Its most common uses are intraoperatively to counteract the vasodilatory effects of anesthetics and in septic shock where its lack of beta-adrenergic activity may help limit deleterious increases in heart rate seen with other agents. Isoproterenol is another synthetic catecholamine with dominant beta-1 and beta-2 activity. Its previous indications for use have largely been supplanted by dobutamine. Due to its powerful chronotropic effects, it can be useful in the management of bradyarrhythmias and torsades de pointes ventricular tachycardia (for overdrive pacing), but otherwise it has no specific role in the management of circulatory shock.

Vasopressin levels in septic shock have been shown to be significantly suppressed.⁴¹³ Studies have shown that intravenous infusion of vasopressin into patients with septic shock results in a profound pressor response.⁴¹⁴ This profound pressor response occurs despite the absence of such an effect with even larger amounts of vasopressin in normotensive patients. Investigators have also documented efficacy in other vasodilatory shock states with refractory hypotension including milrinone-induced shock in severe heart failure,⁴³⁶ postcardiotomy vasodilatory shock,⁴³⁷ unstable brain dead organ donors,⁴³⁸ and late phase hemorrhagic shock.⁴¹⁶ Vasopressin (0.1 to 1 U/mL in normal saline or D5W) may be initiated at 0.02 to 0.04 U/min and titrated up every 20 to 30 minutes to 0.1 to 0.12 U/min. Few patients will respond with higher doses. It is of note that in large doses, vasopressin may produce bradycardia, minor arrhythmias, premature atrial contraction, heart block, peripheral vascular constriction or collapse, coronary insufficiency, decreased cardiac output, myocardial ischemia, and myocardial infarction. In patients with coronary artery disease, even small doses of the drug can precipitate angina. At the upper end of dosing, a significant subset of patients may develop digital, mesenteric, or myocardial ischemia, so it is imperative to use the minimal amount of vasopressin possible to achieve desired blood pressure goals. Published data suggest vasopressin can be used for up to 4 to 6 days if necessary. A

randomized, blinded study of vasopressin treatment of septic shock has shown that the addition of vasopressin (versus norepinephrine) to open label vasopressors offered no overall advantage.⁴³⁹ Because of the limited experience with this compound and the relatively longer half-life of the drug, vasopressin should be utilized only after hemodynamic stabilization with standard agents (catecholamines) has been attempted.

CONCLUSION

Although the syndrome of shock ultimately involves common late pathologic elements, the early pathophysiologic processes underlying different conditions resulting in circulatory shock are both diverse and complex. Our concepts of shock, which once focused on broad cardiovascular physiologic mechanisms, have more recently centered on issues of microvascular function and cellular metabolism. In the future, this focus may evolve toward questions of altered cellular gene expression in a variety of tissues. Advances in therapy have developed in parallel to these changes in our understanding of shock pathophysiology. Early work on the therapy of shock concentrated on correcting hemodynamic derangements through the use of vasopressors and inotropes. Clinical trials over decades have centered on anticytokines such as anti-TNF α and various novel resuscitative compounds. The most advanced experimental therapies involve the direct manipulation of gene expression via antisense oligonucleotides and transcription factor inhibitors. Despite these advances, however, many questions remain. Only ongoing basic research and clinical trials will answer them.

KEY POINTS

- Shock is the final pathway through which a variety of pathologic processes lead to cardiovascular failure and death.
- Shock is the state in which the profound and widespread reduction of effective tissue perfusion leads to cellular injury. The inability of cells to obtain or utilize oxygen in sufficient quantity to optimally meet their metabolic requirements is common to all forms of shock. Hypotension alone does not define shock.
- Based on hemodynamic characteristics, shock is categorized as hypovolemic, cardiogenic, extracardiac obstructive, or distributive.
- Although one hemodynamic categorization dominates, most forms of clinical shock involve some cardiovascular characteristics of several categories.
- The clinical picture of shock is dependent on the etiology, the magnitude of the injury or insult, and the degree of physiologic compensation. Physiologic compensation is determined by the time course of the development of shock and the preexisting cardiovascular reserve.

KEY POINTS (Continued)

- The systemic hemodynamic aspects of shock can be described by the interactive contributions of cardiac and vascular function to blood pressure and cardiac output.
- Physiologically, blood pressure is dependent on cardiac output and vascular resistance; cardiac output is not dependent on blood pressure.
- Failure to maintain the blood pressure required for autoregulation during hypodynamic circulatory shock indicates a severe reduction in cardiac output.
- In a closed cardiovascular circuit, cardiac output as determined by heart rate, preload, afterload, and contractility equals venous return as determined by venous pressure (mean circulatory pressure), right atrial pressure, and venous resistance. Total systemic perfusion is therefore dependent on cardiac-vascular interactions.
- In addition to sufficient cardiac output at sufficient pressure, effective perfusion requires normal local and systemic microvascular function resulting in the appropriate distribution of cardiac output.
- During hypovolemic and other forms of hypodynamic shock, extrinsic blood flow regulatory mechanisms overwhelm the autoregulatory response of most vascular beds. Blood flow to vital organs such as the heart and brain is relatively well preserved due to dominant autoregulatory control.
- During distributive shock, particularly septic shock, organ blood flow is disturbed at higher mean arterial pressures, suggesting a primary defect of microvascular function.
- Cellular dysfunction and organ failure in shock involves the interactions of cellular ischemia, circulating or local inflammatory mediators, and free radical injury.
- All compensatory responses to shock support oxygen delivery to vital tissues. The mechanisms include support of venous pressure, maximization of cardiac function, redistribution of perfusion to vital organs, and optimization of oxygen unloading.
- Circulatory shock may be associated with encephalopathy, adult respiratory distress syndrome, acute tubular necrosis, ischemic hepatitis or intrahepatic cholestasis, thrombocytopenia, immunosuppression, and multiple organ dysfunction syndrome.
- Because early recognition and treatment are the keys to improved survival, the diagnosis of shock is primarily based on clinical criteria. Laboratory and radiologic data are used to confirm the diagnosis and to help clarify etiology.
- Clinically, shock is characterized by physiologic compensatory responses including tachycardia, tachypnea, oliguria, and signs of physiologic decompensation, particularly hypotension.

Continued on following page

KEY POINTS (Continued)

- Shock should be managed in an intensive care unit with continuous monitoring and close nursing support. Patients whose etiologic diagnosis is in doubt, whose hemodynamic instability does not quickly resolve with intravenous fluids, or who are medically complicated should undergo noninvasive (echo) or invasive hemodynamic monitoring with arterial and centrally placed catheters. Pulmonary artery catheters remain a reasonable option in some cases.
- The basic goal of therapy of circulatory shock is the restoration of effective perfusion to vital organs and tissues prior to the onset of cellular injury.
- The specific aims of resuscitation of shock include support of mean blood pressure above 60 to 65 mmHg, maintenance of a cardiac index greater than 2.1 L/min/m², and restriction of arterial lactate concentrations to less than 2.2 mmol/L.

Myocarditis

CONCLUSION

Cardiogenic shock is the syndrome that ensues when the heart is unable to deliver enough blood to maintain adequate tissue perfusion. Acute myocardial infarction (MI) is the leading cause, but other potential etiologic factors need to be considered.^{1,2} Without prompt diagnosis and appropriate management, morbidity and mortality rates are substantial, approaching 60% for all age groups.^{2,3} Rapid evaluation and prompt initiation of supportive measures and definitive therapy in patients with cardiogenic shock may improve both early and long-term outcomes.

DEFINITION

The clinical definition of cardiogenic shock includes decreased cardiac output and evidence of tissue hypoxia in the presence of adequate intravascular volume. The diagnosis of circulatory shock (**Box 22.1**) is made at the bedside by the presence of hypotension along with a combination of clinical signs indicative of poor tissue perfusion, including oliguria, clouded sensorium, and cool, mottled extremities. Hemodynamic criteria include sustained hypotension (systolic blood pressure < 90 mm Hg for at least 30 minutes) and a reduced cardiac index (<2.2 L/min/m²) in the presence of elevated filling pressures (pulmonary capillary occlusion pressure > 15 mm Hg).⁴ Cardiogenic shock is diagnosed after documentation of myocardial dysfunction and exclusion or correction of factors such as hypovolemia, hypoxia, and acidosis.

EPIDEMIOLOGY

Pump failure due to cardiogenic shock has long been known to carry a high mortality rate. The seminal article outlining prognosis after MI was a single center series of 250 patients reported by Killip in 1967.⁵ Killip divided patients into four classes as follows:

Killip class I: no evidence of congestive heart failure

Killip class II: presence of an S₃ gallop and/or bibasilar rales

Killip class III: pulmonary edema (rales greater than halfway up the lung fields)

Killip class IV: cardiogenic shock

Nineteen percent of the 250 patients were in class IV at presentation, and their mortality rate was 81%.⁵

With the advent of right-sided heart catheterization, Forrester and Swan defined hemodynamic subsets after MI analogous to the clinical subsets outlined by Killip.⁴ Subset I consisted of patients with normal pulmonary capillary wedge pressure (PCWP) and cardiac output, subset II consisted of patients with elevated PCWP and normal cardiac output, subset III consisted of patients with normal PCWP and decreased cardiac output, and subset IV consisted of patients with elevated PCWP and decreased cardiac output.⁴

Despite advances in management of heart failure and acute MI, the mortality rate of patients with cardiogenic shock has remained high.^{2,6-8} Data suggest an increase in

Cardiac index < 2.2 L/min/m²
Pulmonary artery occlusion pressure > 15 mm Hg

survival in the 1990s, coincident with the use of reperfusion strategies.⁷⁻⁹ Cardiogenic shock, however, remains the most common cause of death in hospitalized patients with acute MI.

INCIDENCE

Accurate determination of the precise incidence of cardiogenic shock is difficult because patients who die of MI prior to reaching the hospital generally do not receive this diagnosis.^{6,10-13} Nonetheless, estimates from a variety of sources have been fairly consistent. The Worcester Heart Attack Study,⁶ a community-wide analysis, found an incidence of cardiogenic shock of 7.5%, an incidence that remained fairly stable from 1975 to 1997.^{6,9} The incidence was similar in the randomized GUSTO (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) trial (7.2%),¹⁴ in other multicenter thrombolytic trials,¹⁰⁻¹² and in patients with ST-segment elevation MI in the National Registry of Myocardial Infarction (NRFMI) database from 1995 to 2004 (8.6%).⁷ More recently, however, the incidence of cardiogenic shock has fallen from about 8% to about 6% of MIs, with most of the change resulting from a decrease in cardiogenic shock developing after initial presentation, supporting the notion that early revascularization strategies are an important contributor to the decline.³

ETIOLOGY

The most common cause of cardiogenic shock is left ventricular failure in the setting of an extensive acute MI, although a smaller infarction in a patient with previously compromised left ventricular function may also precipitate shock. Cardiogenic shock can also be caused by mechanical complications such as acute mitral regurgitation, rupture of the interventricular septum, or rupture of the free wall—or by large right ventricular infarctions. In a report of the SHOCK (SHould we emergently revascularize Occluded Coronaries for shock) trial registry of 1160 patients with cardiogenic shock,² 78.5% of patients had predominant left ventricular failure, 6.9% had acute mitral regurgitation, 3.9% had ventricular septal rupture, 2.8% had isolated right ventricular shock, 1.4% had tamponade or cardiac rupture, and 6.5% had shock resulting from other causes.

Box 22.2 Causes of Cardiogenic Shock**Acute Myocardial Infarction**

Pump failure
Large infarction
Smaller infarction with preexisting left ventricular dysfunction
Infarct extension
Reinfarction
Infarct expansion
Mechanical complications
Acute mitral regurgitation due to papillary muscle rupture
Ventricular septal defect
Free wall rupture
Pericardial tamponade
Right ventricular infarction

Other Conditions

End-stage cardiomyopathy
Myocarditis
Myocardial contusion
Prolonged cardiopulmonary bypass
Septic shock with severe myocardial depression
Left ventricular outflow tract obstruction
Aortic stenosis
Hypertrophic obstructive cardiomyopathy
Obstruction to left ventricular filling
Mitral stenosis
Left atrial myxoma
Acute mitral regurgitation (chordal rupture)
Acute aortic insufficiency

Other causes of cardiogenic shock include myocarditis, end-stage cardiomyopathy, myocardial contusion, septic shock with severe myocardial depression, myocardial dysfunction after prolonged cardiopulmonary bypass, valvular heart disease, and hypertrophic obstructive cardiomyopathy (Box 22.2). An important consideration is that some cardiogenic shock may have an iatrogenic component. Early diagnosis of impending shock or of patients at high risk for development of shock is essential, both to speed intervention and to avoid therapies that may worsen hemodynamics. In many cases of cardiogenic shock in the setting of MI, the diagnosis is not made until the patient has been triaged and admitted to an inpatient setting. Patients may have received early beta blockade or angiotensin-converting enzyme inhibition, therapies that may impact hemodynamics substantially.

Patients may have cardiogenic shock at initial presentation, but most do not; shock usually evolves over several hours,^{15,16} suggesting that early treatment may potentially prevent shock. In fact, some data indicate that early thrombolytic therapy may decrease the incidence of cardiogenic shock.¹⁷ In the SHOCK trial registry, 75% of patients developed cardiogenic shock within 24 hours after presentation, with a median delay of 7 hours.² Results from the GUSTO trial were similar;¹³ among patients with shock, 11% were in shock on arrival and 89% developed shock after admission.

Risk factors for the development of cardiogenic shock in MI generally parallel those for left ventricular dysfunction

and the severity of coronary artery disease. Shock is more likely to develop in patients who are elderly, are diabetic, and have anterior MI.^{5,15,18,19} Patients with cardiogenic shock are also more likely to have histories of previous infarction, peripheral vascular disease, and cerebrovascular disease.^{18,19} Decreased ejection fractions and larger infarctions (as evidenced by higher cardiac enzymes) are also predictors of the development of cardiogenic shock.^{18,19} Analysis from the GUSTO-3 trial has identified age, lower systolic blood pressure, heart rate, and Killip class as significant predictors of the risk for development of cardiogenic shock after presentation with acute MI.²⁰ Use of a predictive scoring system derived from this study may be useful in identifying patients at high risk for the development of cardiogenic shock and targeting such patients for closer monitoring.²⁰

Cardiogenic shock is most often associated with anterior MI. In the SHOCK trial registry, 55% of infarctions were anterior, 46% were inferior, 21% were posterior, and 50% were in multiple locations.² These findings were consistent with those in other series.²¹ Angiographic evidence most often demonstrates multivessel coronary disease (left main occlusion in 20% of patients, three-vessel disease in 64%, two-vessel disease in 23%, and one-vessel disease in 13% of patients).²² The high prevalence of multivessel coronary artery disease is important because compensatory hyperkinesis normally develops in myocardial segments that are not involved in an acute MI, and this response helps maintain cardiac output. Failure to develop such a response, because of previous infarction or high-grade coronary stenoses, is an important risk factor for cardiogenic shock and death.^{16,23}

PATHOGENESIS

SYSTEMIC EFFECTS

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by MI or ischemia. The myocardial dysfunction resulting from ischemia worsens that ischemia, creating a downward spiral²⁴ (Fig. 22.1). When a critical mass of ischemic or necrotic left ventricular myocardium fails to pump, stroke volume and cardiac output decrease. Myocardial perfusion, which depends on the pressure gradient between the coronary arterial system and the left ventricle and on the duration of diastole, is compromised by hypotension and tachycardia, exacerbating ischemia. The increased ventricular diastolic pressures caused by pump failure reduce coronary perfusion pressure, and the additional wall stress elevates myocardial oxygen requirements, further worsening ischemia. Decreased cardiac output also compromises systemic perfusion.

When myocardial function is depressed, several compensatory mechanisms are activated, including sympathetic stimulation to increase heart rate and contractility and renal fluid retention to increase preload. These compensatory mechanisms may become maladaptive and can actually worsen the situation when cardiogenic shock develops. Increased heart rate and contractility increase myocardial oxygen demand and exacerbate ischemia. Fluid retention and impaired diastolic filling caused by tachycardia and ischemia may result in pulmonary congestion and hypoxia. Vasoconstriction to maintain blood pressure increases

Figure 22.1 The “downward spiral” in cardiogenic shock. Cardiac dysfunction is usually initiated by myocardial infarction or ischemia. When a critical mass of left ventricular myocardium fails to pump, stroke volume and cardiac output decrease. Myocardial perfusion is compromised by hypotension and tachycardia, exacerbating ischemia. The increased ventricular diastolic pressures that result from pump failure further reduce coronary perfusion pressure, and the additional wall stress elevates myocardial oxygen requirements, also worsening ischemia. Decreased cardiac output also compromises systemic perfusion, which can lead to lactic acidosis and further compromise of systolic performance. When myocardial function is depressed, several compensatory mechanisms are activated, including sympathetic stimulation to increase heart rate and contractility and renal fluid retention to increase preload. These compensatory mechanisms may become dysfunctional and can actually worsen the situation when cardiogenic shock develops by increasing myocardial oxygen demand and afterload. Thus, myocardial dysfunction resulting from ischemia worsens that ischemia, setting up a vicious cycle that must be interrupted to prevent patient demise. LVEDP: left ventricular end-diastolic pressure. (Modified from Hollenberg SM, Kavinsky CJ, Parrillo JE: Cardiogenic shock. *Ann Intern Med* 1999;131:49.)

myocardial afterload, further impairing cardiac performance and increasing myocardial oxygen demand. This increased demand, in the face of inadequate perfusion, worsens ischemia and begins a vicious cycle that will end in death if not interrupted (see Fig. 22.1). The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock.

Not all patients fit into this classic paradigm. In the SHOCK trial, the average systemic vascular resistance (SVR) was not elevated, and the range of values was wide, suggesting that compensatory vasoconstriction is not universal. Some patients had fever and elevated white blood cell counts along with decreased SVR, suggesting a systemic inflammatory response syndrome.²⁵ This has led to an expansion of the paradigm to include the possibility of the contribution of inflammatory responses to vasodilation and myocardial stunning, leading clinically to persistence of shock (Fig. 22.2).²⁵ Supporting this notion is the fact that the mean ejection fraction in the SHOCK trial was only moderately decreased (30%), suggesting that mechanisms other than pump failure were operative.²⁵ Immune activation appears to be common to a number of different forms of shock. Activation of inducible nitric oxide synthase (iNOS) with production of nitric oxide and peroxynitrate has been proposed as one potential mechanism.

MYOCARDIAL PATHOLOGY

Cardiogenic shock is characterized by both systolic and diastolic myocardial dysfunction.^{16,26} Progressive myocardial necrosis has been observed consistently in clinical and pathologic studies of patients with cardiogenic shock.^{16,27} Patients who develop shock after admission often have evidence of infarct extension, which can result from reocclusion of a transiently patent infarct artery, propagation of

intracoronary thrombus, or a combination of decreased coronary perfusion pressure and increased myocardial oxygen demand.^{18,19} Myocytes at the border zone of an infarction are more susceptible to additional ischemic episodes; therefore, these adjacent segments are at particular risk.²⁸ Mechanical infarct expansion, which is seen most dramatically after extensive anterior MI, can also contribute to late development of cardiogenic shock.^{18,29}

Ischemia remote from the infarct zone may be particularly important in producing systolic dysfunction in patients with cardiogenic shock.^{23,30} Patients with cardiogenic shock usually have multivessel coronary artery disease,^{2,16} with limited vasodilator reserve, impaired autoregulation, and consequent pressure-dependent coronary flow in several perfusion territories.³¹ Hypotension and metabolic derangements thus have the potential to impair the contractility of noninfarcted myocardium in patients with shock.³² This can limit hyperkinesis of uninvolved segments, a compensatory mechanism typically seen early after MI.^{23,30}

Myocardial diastolic function is also impaired in patients with cardiogenic shock. Myocardial ischemia causes decreased compliance, increasing the left ventricular filling pressure at a given end-diastolic volume.^{33,34} Compensatory increases in left ventricular volumes to maintain stroke volume further increase filling pressures. Elevation of left ventricular pressures can lead to pulmonary edema and hypoxemia (see Fig. 22.1).

In addition to abnormalities in myocardial performance, valvular abnormalities can contribute to increased pulmonary congestion. Papillary muscle dysfunction caused by ischemia is common and can lead to substantial increases in left atrial pressure; the degree of mitral regurgitation may be lessened by afterload reduction. This mechanism is distinct from complete rupture of the papillary muscle, a mechanical complication that presents dramatically, with pulmonary edema and cardiogenic shock.

Figure 22.2 Expansion of the pathophysiologic paradigm of cardiogenic shock to include the potential contribution of inflammatory mediators. Inhibition of nitric oxide, however, has not been shown to be beneficial in patients with cardiogenic shock.¹⁴⁹ iNOS, inducible nitric oxide synthase; LVEDP, left ventricular end-diastolic pressure; NO, nitric oxide; ONOO⁻, peroxynitrite; SVR, systemic vascular resistance. (Adapted from Hochman JS: Cardiogenic shock complicating acute myocardial infarction: Expanding the paradigm. *Circulation* 2003;107:2999.)

CELLULAR PATHOLOGY

Tissue hypoperfusion and consequent cellular hypoxia lead to anaerobic glycolysis, with depletion of adenosine triphosphate and intracellular energy reserves. Anaerobic glycolysis also causes accumulation of lactic acid and resultant intracellular acidosis. Failure of energy-dependent ion transport pumps decreases transmembrane potential, causing intracellular accumulation of sodium and calcium and myocyte swelling.³⁵ Cellular ischemia and intracellular calcium accumulation can activate intracellular proteases.³⁶ If the ischemia is severe and prolonged enough, myocardial cellular injury can become irreversible, with the classic pattern of myonecrosis: mitochondrial swelling, accumulation of denatured proteins and chromatin in the cytoplasm, lysosomal breakdown, and fracture of the mitochondria, nuclear envelope, and plasma membrane.^{35,36}

Accumulating evidence indicates that apoptosis (programmed cell death) may also contribute to myocyte loss in MI.^{28,36,37} Although myonecrosis clearly outweighs apoptosis in the core of an infarcted area, evidence for apoptosis has been found consistently in the border zone of infarcts after ischemia and reperfusion and sporadically in areas remote from the ischemia area.^{28,37} Activation of inflammatory cascades, oxidative stress, and stretching of myocytes have been proposed as mechanisms that activate the apoptotic pathways.^{36,37} Although the magnitude of apoptotic cell loss in MI remains uncertain, inhibitors of apoptosis have been found to attenuate myocardial injury in animal models of postischemic reperfusion; these inhibitors may also have therapeutic potential for myocyte salvage after large infarctions.³⁷

REVERSIBLE MYOCARDIAL DYSFUNCTION

A key to understanding the pathophysiology and treatment of cardiogenic shock is to realize that large areas of nonfunctional but viable myocardium can also cause or contribute to the development of cardiogenic shock in patients after MI (Fig. 22.3). This reversible dysfunction can be described in two main categories: stunning and hibernation.

Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal blood flow; eventually, however, myocardial performance recovers completely.³⁸ Originally defined in animal models of ischemia and reperfusion,³⁹ stunning has been recognized in the clinical arena.^{38,40} Direct evidence for myocardial stunning in humans has been found using positron emission tomography (PET) scanning in patients with persistent wall motion abnormalities after angioplasty for acute coronary syndromes; perfusion measured by ¹³N-ammonia was normal in the presence of persistent contractile dysfunction.⁴¹ The pathogenesis of stunning has not been conclusively established but appears to involve a combination of oxidative stress,⁴² perturbation of calcium homeostasis, and decreased myofilament responsiveness to calcium.^{38,43,44} In addition to these direct effects, data from studies in isolated cardiac myocytes suggest that circulating myocardial depressant substances may contribute to contractile dysfunction in myocardial stunning.⁴⁵ The intensity of stunning is

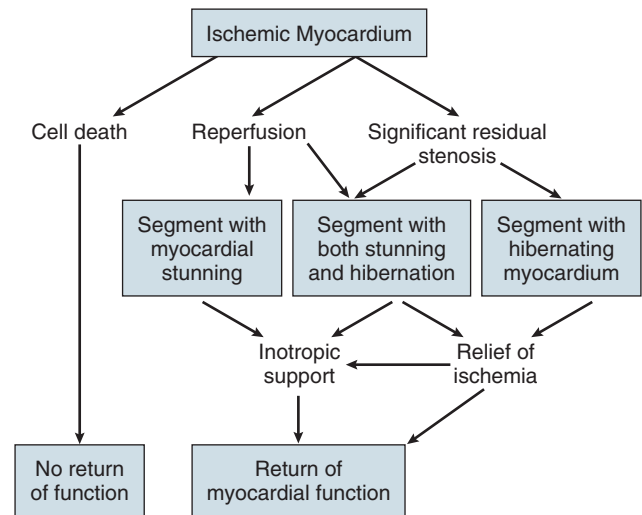

Figure 22.3 Possible outcomes after myocardial ischemia. After myocardial ischemia, either necrosis or reversible dysfunction may occur. Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal flow. These segments respond to inotropes and will recover function if supported. Hibernating myocardium is a state of persistently impaired myocardial function at rest due to residual stenosis; function can be restored to normal by relieving ischemia. Repetitive episodes of stunning can coexist with or mimic myocardial hibernation. The concept that stunned or hibernating segments can recover contractile function emphasizes the importance of measures to support hemodynamics in patients with cardiogenic shock. (Modified from Hollenberg SM, Kavinsky CJ, Parrillo JE: Cardiogenic shock. *Ann Intern Med* 1999;131:50.)

determined primarily by the severity of the antecedent ischemic insult.³⁸

Myocardial hibernation comprises segments with persistently impaired function at rest due to severely reduced coronary blood flow; inherent in the definition of hibernating myocardium is the notion that function can be normalized by improving blood flow.⁴⁶⁻⁴⁸ Hibernation can be seen as an adaptive response to reduce contractile function of hypoperfused myocardium and restore equilibrium between flow and function, thereby minimizing the potential for ischemia or necrosis.⁴⁹ Revascularization of hibernating myocardium can lead to improved myocardial function,⁵⁰ and improved function appears to translate into improved prognosis.^{51,52}

Although hibernation is conceptually and pathophysiologically different from myocardial stunning, the two conditions are difficult to distinguish in the clinical setting and may in fact coexist.^{38,52} Repetitive episodes of myocardial stunning can coexist with or mimic myocardial hibernation.^{38,46,53} Consideration of myocardial stunning and hibernation is vital in patients with cardiogenic shock because of their therapeutic implications. Hibernating myocardium improves with revascularization, and stunned myocardium retains inotropic reserve and can respond to inotropic stimulation.³⁸ In addition, the fact that the severity of the antecedent ischemic insult determines the intensity of stunning³⁸ provides one of the rationales for reestablishment of patency of occluded coronary arteries in patients with cardiogenic shock. Finally, the notion that some myocardial tissue may recover function emphasizes the importance of measures

to support hemodynamics and thus minimize myocardial necrosis in patients with shock.

CLINICAL ASSESSMENT

EVALUATION

Cardiogenic shock is an emergency. The clinician must initiate therapy before shock irreversibly damages vital organs; at the same time, he or she must perform the clinical assessment required to understand the cause of shock and to target therapy to that cause. A practical approach is to make a rapid initial evaluation on the basis of a limited history, physical examination, and specific diagnostic procedures (Fig. 22.4).²⁴ Cardiogenic shock is diagnosed after documentation of myocardial dysfunction and exclusion of alternative causes of hypotension such as hypovolemia, hemorrhage, sepsis, pulmonary embolism, tamponade, aortic dissection, and preexisting valvular disease.

Patients with shock are usually ashen or cyanotic and can have cool skin and mottled extremities. Cerebral hypoperfusion may cloud the sensorium. Pulses are rapid and faint and may be irregular in the presence of arrhythmias. Jugular venous distention and pulmonary rales are usually present, although their absence does not exclude the diagnosis. A precordial heave resulting from left ventricular dyskinesis may be palpable. The heart sounds may be distant, and third or fourth heart sounds are usually present. A systolic murmur of mitral regurgitation or ventricular septal defect may be

heard, but these complications may occur without an audible murmur.

An electrocardiogram should be performed immediately; other initial diagnostic tests usually include chest radiography and measurement of arterial blood gas, electrolytes, complete blood count, and cardiac enzymes.

Echocardiography is an excellent initial tool for confirming the diagnosis of cardiogenic shock and ruling out other causes of shock (Box 22.3); therefore, early echocardiography should be routine. Echocardiography provides information on overall and regional systolic function, and can rapidly diagnose mechanical causes of shock such as papillary muscle rupture and acute mitral regurgitation, acute ventricular septal defect, and free wall rupture and tamponade.^{54,55} Unsuspected severe mitral regurgitation is not uncommon. In some cases, echocardiography may reveal findings compatible with right ventricular infarction.

Box 22.3 Role of Echocardiography in Cardiogenic Shock

- Evaluate overall systolic performance
- Delineate regional wall motion abnormalities
- Rule out mechanical causes of shock
 - Papillary muscle rupture
 - Ventricular septal rupture
 - Free wall rupture
 - Tamponade
- Diagnose right ventricular infarction

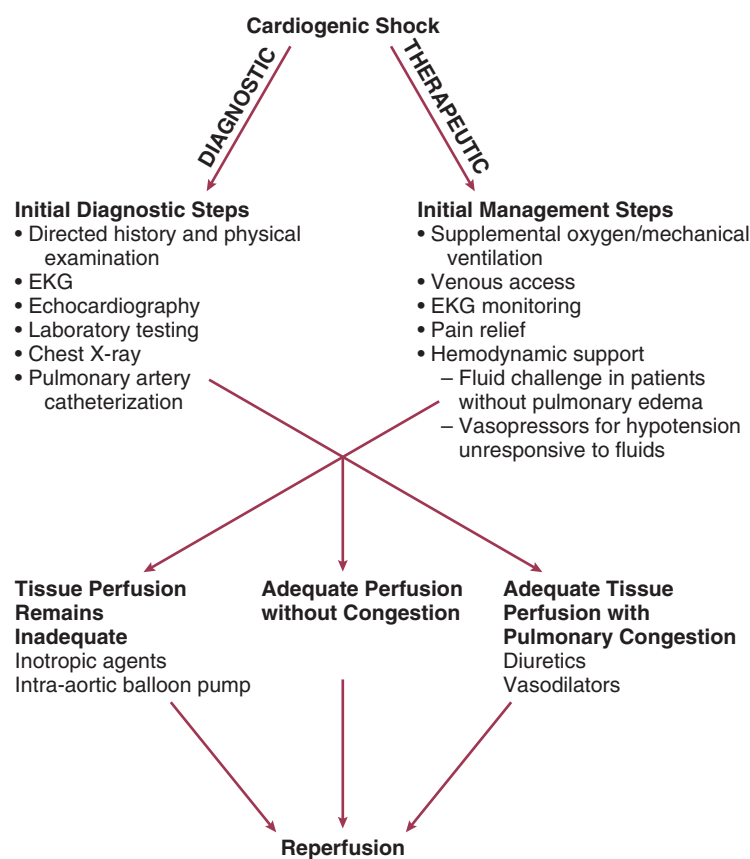

Figure 22.4 An approach to the diagnosis and treatment of cardiogenic shock caused by myocardial infarction. Right ventricular infarction and mechanical complications are discussed in the text. CABG, coronary artery bypass grafting; IABP, intra-aortic balloon pumping. (Modified from Hollenberg SM, Kavinsky CJ, Parrillo JE: Cardiogenic shock. *Ann Intern Med* 1999;131:51.)

Invasive hemodynamic monitoring can be quite useful to exclude volume depletion, right ventricular infarction, and mechanical complications.^{16,35} The hemodynamic profile of cardiogenic shock includes a pulmonary capillary occlusion pressure greater than 15 mm Hg and a cardiac index less than 2.2 L/min/m². It should be recognized that optimal filling pressures may be greater than 15 mm Hg in individual patients due to left ventricular diastolic dysfunction. Right-sided heart catheterization may reveal an oxygen step-up diagnostic of ventricular septal rupture or a large v wave that suggests severe mitral regurgitation. The hemodynamic profile of right ventricular infarction includes high right-sided filling pressures in the presence of normal or low occlusion pressures.^{56,57}

Coronary angiography is usually performed as a precedent to revascularization, and will be considered later.

INITIAL MANAGEMENT

Maintenance of adequate oxygenation and ventilation are critical; intubation and mechanical ventilation are often required, if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Central venous and arterial access, bladder catheterization, and pulse oximetry are routine. Electrolyte abnormalities should be corrected. Hypokalemia and hypomagnesemia are predisposing factors to ventricular arrhythmias, and acidosis can decrease contractile function. Relief of pain and anxiety with morphine sulfate (or fentanyl if systolic pressure is compromised) can reduce excessive sympathetic activity and decrease oxygen demand, preload, and afterload. Arrhythmias and heart block may have major effects on cardiac output, and should be corrected promptly with antiarrhythmic drugs, cardioversion, or pacing. Cardiology consultation has been shown to be associated with improved outcomes in patients with MI and is strongly indicated in the setting of cardiogenic shock.⁵⁸ In addition, measures proven to improve outcome after MI, such as nitrates, beta blockers, and angiotensin-converting enzyme inhibitors,⁵⁹ have the potential to exacerbate hypotension in cardiogenic shock and should be stopped until the patient stabilizes.

THERAPY

Following initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed (see Fig. 22.4). If tissue perfusion remains inadequate, inotropic support or intra-aortic balloon pumping (IABP) should be initiated. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics may be employed. Vasodilators can be considered as well, depending on the blood pressure.

The initial approach to the hypotensive patient should include fluid resuscitation unless frank pulmonary edema is present. Patients are commonly diaphoretic and relative hypovolemia may be present. In the original description of hemodynamic subsets in MI, approximately 20% of patients had low cardiac index and low PCWP; most had reduced stroke volume and compensatory tachycardia.⁶⁰ Some of

these patients would be expected to respond to fluid infusion with an increase in stroke volume, although the magnitude of such a response depends on the degree of ischemia and cardiac reserve.

Fluid infusion is best initiated with predetermined boluses titrated to clinical end points of heart rate, urine output, and blood pressure.⁶¹ Ischemia produces diastolic as well as systolic dysfunction, and thus elevated filling pressures may be necessary to maintain stroke volume in patients with cardiogenic shock. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserve should be considered for invasive hemodynamic monitoring. Optimal filling pressures vary from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside, identifying the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with right ventricular infarction.

When arterial pressure remains inadequate, therapy with vasopressor agents, titrated not only to blood pressure but to clinical indices of perfusion and mixed venous oxygen saturation, may be required to maintain coronary perfusion pressure. Maintenance of adequate blood pressure is essential to break the vicious cycle of progressive hypotension with further myocardial ischemia. Norepinephrine is preferable to dopamine for hypotension in this situation. Dopamine acts as both an inotrope (particularly 3-10 µg/kg/minute) and a vasopressor (10-20 µg/kg/minute). Norepinephrine (0.02-1.0 µg/kg/minute) acts primarily as a vasoconstrictor, has a mild inotropic effect, and increases coronary flow. A recent randomized trial comparing norepinephrine and dopamine in 1678 patients with shock found no significant difference in 28-day mortality rate in the overall trial, but a prespecified subgroup analysis did find increased mortality rate with dopamine in the 280 patients with cardiogenic shock.⁶² Phenylephrine, a selective α₁-adrenergic agonist, may be employed to support blood pressure when tachyarrhythmias limit therapy with other vasopressors, although it does not improve cardiac output. Vasopressin, which causes vasoconstriction, has a neutral or slightly depressant effect upon cardiac output, and increases vascular sensitivity to norepinephrine, may be added to catecholamines if needed.

In patients with inadequate tissue perfusion and adequate intravascular volume, cardiovascular support with inotropic agents should be initiated. Dobutamine, a selective β₁-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output without markedly changing heart rate or SVR; it is the initial agent of choice in patients with systolic pressures greater than 90 mm Hg.⁶³⁻⁶⁵ Dobutamine may exacerbate hypotension in some patients and can precipitate tachyarrhythmias. Phosphodiesterase inhibitors such as milrinone increase intracellular cyclic adenosine monophosphate (cAMP) by mechanisms not involving adrenergic receptors, producing both positive inotropic and vasodilatory actions. Milrinone has fewer chronotropic and arrhythmogenic effects than catecholamines.⁶⁶ In addition, because milrinone does not stimulate adrenergic receptors directly, its effects may be additive to those of the catecholamines.⁶⁷ Milrinone, however, has the potential to cause hypotension and has a long half-life; in patients with tenuous clinical status, its use is often reserved for

situations in which other agents have proved ineffective.¹⁶ Standard administration of milrinone calls for a loading dose followed by an infusion, but most clinicians eschew the loading dose in patients with marginal blood pressure.

Levosimendan, a calcium sensitizer, has both inotropic and vasodilatory properties and does not increase myocardial oxygen consumption. Levosimendan reduces the calcium-binding coefficient of troponin C by stabilizing the conformational shape, which enhances myocardial contraction with lower intracellular calcium concentrations.⁶⁸ Several relatively small studies have shown hemodynamic benefits with levosimendan in cardiogenic shock after MI,⁶⁹ one suggesting a better hemodynamic effect than dobutamine,⁷⁰ but survival benefits with use of levosimendan have not been shown in either cardiogenic shock or acute heart failure.⁷¹ Levosimendan has the potential to cause hypotension and thus should be used with some caution in patients with cardiogenic shock. Levosimendan is not available in the United States.

Infusions of vasoactive agents need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring can be extremely useful in allowing optimization of therapy in these unstable patients, because clinical estimates of filling pressure can be unreliable;⁷² in addition, changes in myocardial performance and compliance and therapeutic interventions can change cardiac output and filling pressures precipitously. Optimization of filling pressures and serial measurements of cardiac output (and other parameters, such as mixed venous oxygen saturation) allow for titration of the dosage of inotropic agents and vasopressors to the minimum dosage required to achieve the chosen therapeutic goals. This control minimizes the increases in myocardial oxygen demand and arrhythmogenic potential.^{61,73}

Diuretics should be used to treat pulmonary congestion and enhance oxygenation. Vasodilators should be used with extreme caution in the acute setting owing to the risk of precipitating further hypotension and decreasing coronary blood flow. After blood pressure has been stabilized, however, vasodilator therapy can decrease both preload and afterload. Sodium nitroprusside is a balanced arterial and venous vasodilator that decreases filling pressures and can increase stroke volume in patients with heart failure by reducing afterload.⁷⁴ Nitroglycerin is an effective venodilator that reduces the pulmonary capillary occlusion pressure and can decrease ischemia by reducing left ventricular filling pressure and redistributing coronary blood flow to the ischemic zone.⁷⁵ Both agents may cause acute and rapid decreases in blood pressure and dosages must be titrated carefully; invasive hemodynamic monitoring can be useful in optimizing filling pressures when these agents are used.

THROMBOLYTIC THERAPY

Although it has been demonstrated convincingly that thrombolytic therapy reduces mortality rates in patients with acute MI,^{10,76-78} the benefits of this therapy in patients with cardiogenic shock are less certain. It is clear that thrombolytic therapy can reduce the likelihood of subsequent

development of shock after initial presentation.^{14,76,77,79} This is important because most patients develop cardiogenic shock more than 6 hours after hospital presentation.^{2,14}

Nonetheless, no trials have demonstrated that thrombolytic therapy reduces mortality rate in patients with established cardiogenic shock. The numbers of patients are small because most thrombolytic trials have excluded patients who have cardiogenic shock at presentation.⁸⁰ In the GISSI (Gruppo Italiano per lo Studio della Streptochinasi Nell'Infarto Miocardico) trial,^{10,80} 30-day mortality rates were 69.9% in 146 patients with cardiogenic shock who received streptokinase and 70.1% in 134 patients receiving placebo. The International Study Group reported a mortality rate of 65% in 93 patients with shock treated with streptokinase and a mortality rate of 78% in 80 patients treated with recombinant tissue plasminogen activator (rt-PA).¹² In the GUSTO trial,¹³ 315 patients had shock on arrival; mortality rate was 56% in patients treated with streptokinase and 59% in patients treated with rt-PA.^{14,81}

The failure of thrombolytic therapy to improve survival in patients with cardiogenic shock may seem paradoxical in light of evidence that the absolute reduction in mortality rate with thrombolytics is greatest in those at highest risk at presentation. The meta-analysis performed by the Fibrinolytic Therapy Trialists (FTT) Collaborative Group demonstrated a reduction in mortality rate from 36.1% to 29.7% when thrombolytic therapy was used in patients with initial systolic blood pressures less than 100 mm Hg. In patients with initial heart rates greater than 100 beats per minute the mortality rate decreased from 23.8% to 18.9%.⁸² However, most patients in these subgroups did not meet criteria for cardiogenic shock.

Consideration of the efficacy of thrombolytic therapy once cardiogenic shock has been established makes the disappointing results in this subgroup of patients easier to understand. The degree of reperfusion correlates with outcome,^{79,83} and reperfusion has been shown to be less likely for patients in cardiogenic shock.^{21,83,84} When reperfusion is successful, mortality rate has been shown to be significantly reduced.²¹ The lower rates of reperfusion in patients with shock may explain some of the disappointing results in this subgroup in the thrombolytic trials.

The reasons for decreased thrombolytic efficacy in patients with cardiogenic shock include hemodynamic, mechanical, and metabolic factors. Decreased arterial pressure limits the penetration of thrombolytic agents into a thrombus.⁸⁵ Passive collapse of the infarct artery in the setting of hypotension can also contribute to decreased thrombolytic efficacy, as can acidosis, which inhibits the conversion of plasminogen to plasmin.⁸⁵ Two small studies support the notion that vasopressor therapy to increase aortic pressure improves thrombolytic efficacy.^{86,87}

INTRA-AORTIC BALLOON PUMPING

IABP reduces systolic afterload and augments diastolic perfusion pressure, increasing cardiac output and improving coronary blood flow.^{88,89} These beneficial effects, in contrast to those of inotropic or vasopressor agents, occur without an increase in oxygen demand. IABP is efficacious for initial stabilization of patients with cardiogenic shock.^{90,91} Small

randomized trials in the prethrombolytic era, however, failed to show that IABP alone increases survival.^{92,93} IABP alone does not substantially improve blood flow distal to a critical coronary stenosis.⁹⁴

IABP is probably not best used as an independent modality to treat cardiogenic shock. It may, however, be an essential support mechanism to allow definitive therapeutic measures to be undertaken. In the GUSTO trial, patients who presented with shock and had early IABP placement showed a trend toward lower mortality rates, even after exclusion of patients who underwent revascularization.^{13,95} A similar trend was seen in the SHOCK trial registry, although it did not persist after adjustment for age and catheterization.² Several observational studies have also suggested that IABP can improve outcome in patients with shock, although revascularization procedures are a confounding factor in these studies.⁹⁶⁻⁹⁹ IABP has been shown to decrease reocclusion and cardiac events after emergency angioplasty for acute MI.^{100,101} The TACTICS trial randomized 57 patients with MI complicated by hypotension or cardiogenic shock to IABP or placebo in conjunction with fibrinolysis; the trial was terminated early due to difficulties with enrollment and was thus underpowered.¹⁰² Although there was no difference in the primary end point of 6-month mortality rate (34% versus 43%, $p = 0.23$), patients presenting in Killip class III or IV heart failure showed a trend toward benefit with IABP (39% versus 80%, $p = 0.05$).¹⁰²

REVASCULARIZATION

Pathophysiologic considerations and extensive retrospective data favor aggressive mechanical revascularization for patients with cardiogenic shock due to MI. Emergency percutaneous revascularization is the only intervention to date that has been shown to consistently reduce mortality rates in patients with cardiogenic shock.

DIRECT CORONARY ANGIOPLASTY

Reestablishment of brisk (TIMI [Thrombolysis in Myocardial Infarction] grade 3) flow in the infarct-related artery is an important determinant of left ventricular function and survival after MI.⁷⁹ Direct percutaneous transluminal coronary angioplasty (PTCA) can achieve TIMI grade 3 flow in 80% to 90% of patients with MI¹⁰³⁻¹⁰⁵ compared with rates of 50% to 60% 90 minutes after thrombolytic therapy.^{79,106} In addition to improving wall motion in the infarct territory, increased perfusion of the infarct zone has been associated with augmented contraction of remote myocardium, possibly due to recruitment of collateral blood flow.²³

Use of angioplasty in patients with cardiogenic shock grew out of its use as primary therapy in patients with MI.^{21,107-117} Observational studies from registries of randomized trials, most notably the GUSTO-1 trial, have also reported improved outcomes in patients with cardiogenic shock selected for revascularization,^{14,84,118} and these findings have also been confirmed in reports from NRMI.¹¹⁹

RANDOMIZED STUDIES

Prompt revascularization is the only intervention that has been shown consistently to reduce mortality rates in cardiogenic shock. In the landmark SHOCK trial, patients with

shock caused by left ventricular failure complicating ST-segment elevation myocardial infarction (STEMI) were randomized to emergency revascularization ($n = 152$), accomplished by either coronary artery bypass grafting (CABG) or angioplasty, or initial medical stabilization ($n = 150$). IABPs were used in 86% of patients in both groups. The landmark “Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock” (SHOCK) study^{120,121} was a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management—including IABP and thrombolytic therapy—or to cardiac catheterization with revascularization using PTCA or CABG.¹²⁰ The trial enrolled 302 patients and was powered to detect a 20% absolute decrease in 30-day all-cause mortality rates. Mortality rate at 30 days was 46.7% in patients treated with early intervention and 56% in patients treated with initial medical stabilization, but this difference did not quite reach statistical significance ($p = 0.11$).¹²⁰ It is important to note that the control group (patients who received medical management) had a lower mortality rate than that reported in previous studies; this may reflect the aggressive use of thrombolytic therapy (64%) and balloon pumping (86%) in these control subjects. These data provide indirect evidence that the combination of thrombolysis and IABP may produce the best outcomes when cardiac catheterization is not immediately available. At 6 months, mortality rate in the SHOCK trial was reduced significantly (50.3% compared with 63.1%, $p = 0.027$),¹²⁰ and this risk reduction was maintained at 12 months (mortality rate 53.3% versus 66.4%, $p < 0.03$) (Fig. 22.5).¹²¹ Encouragingly, this 13% absolute improvement in survival remained stable at both 3 and 6 years of follow-up.¹²² In addition, most survivors have good functional status.¹²³

Subgroup analysis showed a substantial improvement in mortality rates in patients younger than 75 years of age at both 30 days (41.4% versus 56.8%, $p = 0.01$) and 6 months

Figure 22.5 Mortality rates in the randomized SHOCK trial at 30 days, 6 months, and 1 year in the early revascularization and optimal medical management groups. (Data from Hochman JS, Sleeper LA, Webb JG, et al: Early revascularization in acute myocardial infarction complicated by cardiogenic shock. *N Engl J Med* 1999;341:625-634; and Hochman JS, Sleeper LA, White HD, et al: One-year survival following early revascularization for cardiogenic shock. *JAMA* 2001;285:190-192.)

(44.9% versus 65.0%, $p = 0.003$).¹²⁰ For patients older than 75, no benefit of revascularization was demonstrated in the SHOCK trial, although this was a small subgroup, and further analysis suggested baseline differences so that the elderly patients randomized to medical therapy appeared to have been a lower-risk group.¹²⁴ In the SHOCK trial registry, elderly patients treated with early revascularization had better outcomes than those treated medically, suggesting that it is possible to select elderly patients who will benefit from aggressive treatment.¹²⁵

The SMASH (Swiss Multicenter Trial of Angioplasty for Shock) trial was independently conceived and had a very similar design, although a more rigid definition of cardiogenic shock resulted in enrollment of sicker patients and a higher mortality rate.¹²⁶ The trial was terminated early due to difficulties in patient recruitment for two different reasons: Early on, several centers declined to participate because it was felt that it would not be ethical to undertake early invasive evaluation in such extremely ill patients, and then, after publication of several encouraging studies documenting the superiority of percutaneous coronary intervention (PCI) over thrombolysis for acute MI, many centers felt that it had become unethical *not* to proceed to early evaluation and revascularization.¹²⁷ In the SMASH trial, although the patient numbers were very small (55 patients in all), an absolute reduction in 30-day mortality rate similar to that seen in the SHOCK trial was observed (69% mortality rate in the invasive group versus 78% in the medically managed group, RR [relative risk] = 0.88, 95% CI [confidence interval] = 0.6-1.2, $p = \text{NS}$ [not significant]).¹²⁶ This benefit was also maintained at 1 year.

When the results of both the SHOCK and SMASH trials are put into perspective with results from other randomized, controlled trials of patients with acute MI, an important point emerges: Despite the moderate *relative* risk reduction (for the SHOCK trial, RR 0.72, CI 0.54-0.95; for the SMASH trial, RR 0.88, CI 0.60-1.20) the *absolute* benefit is important, with 9 lives saved for 100 patients treated at 30 days in both trials, and 13.2 lives saved for 100 patients treated at 1 year in the SHOCK trial. This latter figure corresponds to a number needed to treat of 7.6, one of the lowest figures ever observed in a randomized, controlled trial of cardiovascular disease. In our judgment, these data strongly support the superiority of a strategy of early revascularization in most patients with cardiogenic shock (see Fig. 22.4). In the latest ACC/AHA guidelines for the management of acute MI, primary coronary intervention was given a class I indication for patients younger than 75 and a class IIa indication for patients older than 75.¹²⁸

CORONARY ARTERY BYPASS SURGERY

Analysis of the SHOCK trial helps to define the indications for CABG in the setting of cardiogenic shock. CABG should be the first line of therapy offered in cases of left main artery disease or triple-vessel disease as well as in cases in which the patient has sustained mechanical complications necessitating surgical repair. In patients with multivessel disease in the SHOCK trial, complete revascularization was achieved more frequently (87% versus 23%). Long-term mortality rates were similar in the CABG and PCI groups despite worse coronary anatomy and more diabetes in the surgical group.¹²⁹

OTHER CAUSES OF CARDIOGENIC SHOCK

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in up to 30% of patients with inferior infarction and is clinically significant in 10%.¹³⁰ Patients present with hypotension, elevated jugular venous pressure, and clear lung fields. The diagnosis is made by identifying ST-segment elevation in right precordial leads or by characteristic hemodynamic findings on right-sided heart catheterization (elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate depressed right ventricular contractility.⁵⁷ Patients with cardiogenic shock on the basis of right ventricular infarction have a better prognosis than those with left-sided pump failure.¹³⁰ This difference may be due in part to the fact that right ventricular function tends to return to normal over time with supportive therapy,¹³¹ although such therapy may need to be prolonged.

Supportive therapy for patients with right ventricular infarction begins with maintenance of right ventricular preload with fluid administration. In some cases, however, fluid resuscitation may increase pulmonary capillary occlusion pressure but may not increase cardiac output, and overdistention of the right ventricle can compromise left ventricular filling and cardiac output.¹³¹ Inotropic therapy with dobutamine may be more effective in increasing cardiac output in some patients, and monitoring with serial echocardiograms may also be useful to detect right ventricular overdistention.¹³¹ Maintenance of atrioventricular synchrony is also important in these patients to optimize right ventricular filling.⁵⁷ For patients with continued hemodynamic instability, IABP may be useful, particularly because elevated right ventricular pressures and volumes increase wall stress and oxygen consumption and decrease right coronary perfusion pressure, exacerbating right ventricular ischemia.

Reperfusion of the occluded coronary artery is also crucial. Restoration of normal flow by direct angioplasty resulted in dramatic recovery of right ventricular function and a mortality rate of only 2%, whereas unsuccessful reperfusion was associated with persistent hemodynamic compromise and a mortality rate of 58%.¹³² Prompt revascularization of patients with right ventricular infarction is a class I recommendation in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the treatment of acute MI.¹³³

ACUTE MITRAL REGURGITATION

Ischemic mitral regurgitation is usually associated with inferior MI and ischemia or infarction of the posterior papillary muscle, which has a single blood supply, usually from the posterior descending branch of a dominant right coronary artery.¹³⁴ Papillary muscle rupture typically occurs 2 to 7 days after acute MI and presents dramatically with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of rapid equalization of pressures in the left atrium and left ventricle.

More importantly, the murmur may be soft or inaudible, especially when cardiac output is low.¹³⁵

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes afterload reduction with nitroprusside and IABP as temporizing measures. Inotropic or vasopressor therapy may also be needed to support cardiac output and blood pressure. Definitive therapy, however, is surgical valve repair or replacement, which should be undertaken as soon as possible because clinical deterioration can be sudden.^{135,136} Although mortality rate is 20% to 40%, survival and ventricular function are improved compared with medical therapy.¹³⁷

VENTRICULAR SEPTAL RUPTURE

Patients who have ventricular septal rupture have severe heart failure or cardiogenic shock, with a pansystolic murmur and a parasternal thrill. The hallmark finding is a left-to-right intracardiac shunt ("step-up" in oxygen saturation from right atrium to right ventricle). On pulmonary artery catheter tracing, it can be difficult to distinguish ventricular septal rupture from mitral regurgitation, because both can produce dramatic v waves. The diagnosis is most easily made with echocardiography.

Rapid stabilization, using IABP and pharmacologic measures followed by operative repair, is the only viable option for long-term survival. Because perforations are exposed to shear forces, the rupture site can expand abruptly. Repair can be technically difficult owing to the need to suture in areas of necrosis. Surgical mortality rate is 20% to 50%, especially for serpiginous inferoposterior ruptures, which typically are less well circumscribed than anteroapical ruptures. Right ventricular function is an important determinant of outcome in this setting. Timing of surgery has been controversial, but guidelines now recommend that operative repair should be undertaken early, within 48 hours of the rupture.⁵⁹ Placement of a septal occluding device may be helpful in selected patients.

FREE WALL RUPTURE

Ventricular free wall rupture usually occurs during the first week after MI; the classic patient is elderly, female, and hypertensive. The early use of thrombolytic therapy reduces the incidence of cardiac rupture, but late use may increase the risk, particularly in older patients.¹³⁸ Free wall rupture presents as a catastrophic event with a pulseless rhythm. Salvage is possible with prompt recognition, pericardiocentesis to relieve acute tamponade, and thoracotomy with repair.¹³⁹

MYOCARDIAL DYSFUNCTION AFTER CARDIOPULMONARY BYPASS

Transient depression of ventricular contractility is common after cardiopulmonary bypass, and can represent a significant clinical problem. The differential diagnosis includes inadequate operation, cardiac tamponade (which may be localized and difficult to detect), and increased right

ventricular afterload, but most cases likely result from myocardial stunning. The heart is rendered globally ischemic during aortic cross-clamping and then reperfused, and because demonstrable myocardial necrosis is rare, stunning can be implicated. Stunning after bypass has been documented in a study in which an ultrasonic probe was left on the epicardial surface for 2 to 3 days in 31 patients following bypass surgery; left ventricular wall thickening fell after surgery, reached a nadir at 2 to 6 hours, and subsequently improved, usually returning to baseline by 24 to 48 hours.¹⁴⁰

The degree of myocardial dysfunction after cardiac surgery is variable, and may depend on the cardioplegia solution, the method of administration (antegrade or retrograde), the mode of administration (continuous or intermittent), and the temperature of the solution and of the patient during surgery.³⁸ In the clinical setting, transient depression of ventricular contractility is common and usually reversible within 24 to 48 hours. The depression of contractility can be severe to cause cardiogenic shock. In this event, therapy with inotropic agents, vasodilators, and IABP is necessary. Occasionally, even a left ventricular assist device may be employed.⁴⁰ Better understanding of the mechanisms of post-cardiopulmonary bypass myocardial dysfunction may lead to better preventive and therapeutic approaches.

MYOCARDITIS

Acute myocarditis can be benign and self-limited or fulminant, with severe congestive heart failure or atrial and ventricular arrhythmias. After acute myocarditis, patients can recover completely, or they can have severe left ventricular dysfunction. In some patients with acute inflammatory myocarditis, an aberrant immune response occurs, with continuing inflammation, and this can result in the eventual development of a dilated cardiomyopathy.

Evidence exists that some patients with myocarditis will benefit from immunosuppressive therapy, but how to identify which patients should be treated remains controversial. A trial initiated at the National Institutes of Health randomized 102 patients with dilated cardiomyopathy, no significant coronary artery disease, and ejection fraction less than 35% to oral prednisone or placebo.¹⁴¹ The prospectively defined end point, an increase in radionuclide-measured ejection fraction of more than 5 percentage points, was observed in 53% of patients treated with prednisone compared to only 27% of control subjects at 3 months ($p < 0.05$), but the improvement did not persist at 9 months when patients were switched to alternate-day prednisone therapy.¹⁴¹ Another clinical trial of immunosuppressive therapy for myocarditis showed no improvement in mean ejection fraction with immunosuppression, although the admission criteria in this trial were quite restrictive, the therapeutic regimens heterogeneous, and the incidence of definitive myocarditis uncertain.¹⁴² We advocate consideration of corticosteroids in patients with myocarditis who do not respond to conventional heart failure therapies.

Although it might seem that patients with fulminant myocarditis might be the best candidates for immunosuppressive therapy, a recent series confounds this notion by reporting excellent long-term survival in patients with

Figure 22.6 The TandemHeart percutaneous left ventricular assist device in situ. Blood is removed from the left atrium using a catheter placed from the femoral vein across the interatrial septum and pumped into the femoral artery. (Image courtesy of CardioAssist, Pittsburgh, PA.)

myocarditis and a fulminant course.¹⁴³ Patients with acute myocarditis without a fulminant course had a much worse prognosis in this series,¹⁴³ pointing up the need for further research to identify subgroups of patients with dilated cardiomyopathy who may benefit from adjunctive therapies.

LEFT VENTRICULAR ASSIST DEVICES

In patients with potentially reversible causes of myocardial dysfunction, aggressive cardiovascular support with a combination of inotropic agents and intra-aortic balloon counterpulsation may be required for hours or days to allow sufficient time for recovery. If these measures fail, mechanical circulatory support with left ventricular assist devices (LVADs) can be considered.¹⁴⁴ Mechanical support with LVADs can interrupt the downward spiral of myocardial dysfunction, hypoperfusion, and ischemia in cardiogenic shock, allowing time for recovery of stunned or hibernating myocardium.

Percutaneously implanted LVADs are used in situations of cardiogenic shock, during high-risk percutaneous interventions, in postcardiotomy shock, and in fulminant myocarditis. Two currently approved devices, the TandemHeart (Fig. 22.6) and the Impella (Fig. 22.7), can be placed in the cardiac catheterization laboratory. The TandemHeart device is a bypass system with inflow of oxygenated blood from the left atrium and outflow to the femoral artery using a centrifugal flow pump; it can provide blood flow up to 5 L/minute. The Impella device is inserted across the aortic valve and pumps blood from a distal port from within the

Figure 22.7 The Impella catheter when placed across the aortic valve (left). The inflow port is positioned within the left ventricle, and the outflow port is just above the valve. Impella catheter with introducer and sheath (right). (Images courtesy of Abiomed, Danvers, MA.)

ventricle out to the ascending aorta through a proximal port of the device; there are two versions, one capable of pumping 2.5 L/minute, and one with a larger diameter that can provide up to 5 L/minute, although the actual flow is dependent on afterload. The inflow cannula with its pump is under fluoroscopic guidance. The device sits across the aortic valve. These devices augment cardiac output and blood pressure while decreasing myocardial oxygen demand. Both devices offer the potential for near-complete cardiac support but do require adequate right ventricular function. Known complications of percutaneous LVAD use include limb ischemia and bleeding.

Two recent trials compared the use of IABP to the TandemHeart for patients with cardiogenic shock,^{145,146} and another compared use of the Impella to IABP therapy;¹⁴⁷ the results of these trials were combined in a meta-analysis that included 100 patients.¹⁴⁸ Hemodynamic benefits for the percutaneous LVADs compared with IABP were shown, with higher cardiac indices and mean arterial pressures as well as lower PCWPs. However, LVAD use showed no mortality rate benefit over IABP at 30 days.¹⁴⁸

For patients with end-stage heart failure and refractory shock, a variety of surgically placed assist devices can be employed for circulatory support. These devices retrieve blood from the left ventricular apex and use a pumping device, either continuous or pulsatile, to return the blood into the ascending aorta. Full consideration of these devices is beyond the scope of this chapter; in cardiogenic shock, they are usually used as a bridge to recovery or transplantation, although in other contexts they may be used as destination therapy.

CONCLUSION

Cardiogenic shock remains a prevalent and dangerous syndrome that requires accurate and efficient diagnosis. Mortality rates in patients with cardiogenic shock have improved but remain frustratingly high. Its pathophysiology involves

a downward spiral in which ischemia causes myocardial dysfunction, which in turn worsens ischemia. Areas of nonfunctional but viable myocardium can also cause or contribute to the development of cardiogenic shock. Expedient coronary revascularization is crucial, and the randomized multicenter SHOCK trial¹²⁰ has provided important data that help clarify the appropriate role and timing of revascularization in patients with cardiogenic shock. The potential for reversal of myocardial dysfunction with revascularization provides the rationale for supportive therapy to maintain coronary and tissue perfusion until more definitive revascularization measures can be undertaken. Application of a thorough understanding of the essentials of pathophysiology, diagnosis, and treatment of cardiogenic shock can allow for expeditious management and improved outcomes.

KEY POINTS

- Cardiogenic shock is a state of inadequate tissue perfusion due to cardiac dysfunction. Acute MI is the leading cause.
- The pathogenesis of cardiogenic shock is a “downward spiral” in which MI or ischemia causes myocardial dysfunction and compromised myocardial perfusion, exacerbating ischemia.
- Large areas of nonfunctional but viable myocardium (either stunned, hibernating, or both) can also cause or contribute to the development of cardiogenic shock in patients after MI.
- The challenge in initial management of cardiogenic shock is that evaluation and therapy must begin simultaneously. The clinician must perform the clinical assessment required to understand the cause of shock while initiating supportive therapy before shock causes irreversible damage.
- Thrombolytic therapy alone has less efficacy in patients with cardiogenic shock than in other settings; this is due to a combination of hemodynamic, mechanical, and metabolic factors.
- IABP alone has not been shown to decrease mortality rate in cardiogenic shock, but it may be an essential support mechanism to allow definitive therapeutic measures to be undertaken.
- Pathophysiologic considerations and extensive retrospective data favor aggressive mechanical revascularization for patients with cardiogenic shock due to MI. Results of the recent SHOCK study support

KEY POINTS (Continued)

- a strategy of early revascularization in most patients with cardiogenic shock.
- Other acute mechanical causes of low cardiac output must be excluded. If present, urgent surgery may be required.
- In patients with potentially reversible causes of myocardial dysfunction (including severe myocarditis), aggressive cardiovascular support with a combination of inotropic agents and intra-aortic balloon counterpulsation may be required for hours or days to allow sufficient time for recovery.

SUMMARY

OVERVIEW

This chapter pertains to pathophysiology, assessment, and management of septic shock, the most severe and overt manifestation of the septic condition. This discussion will specifically focus on cardiovascular and hemodynamic aspects. Other critically important elements of sepsis pathophysiology, assessment, and management (i.e., beyond the cardiovascular and hemodynamic aspects) will be addressed in a separate chapter (see Chapter 25, Sepsis and Multiple Organ Dysfunction). This chapter is also focused specifically on the adult patient with septic shock, as principles and evidence may differ in important ways in the pediatric population.

HISTORICAL PERSPECTIVE

The word *sepsis* originated from the Greek language. *Sepsis* was synonymous with putrefaction and pertained to the bacteria-mediated decomposition of organic matter.¹ The term persisted for more than 2700 years with essentially unchanged meaning.² In the twentieth century, our modern understanding of the term *sepsis* became rooted in a disease in which the clinical manifestations were attributed to severe infection and the release of pathogenic bacterial products into the patient's bloodstream.^{3,4}

The term *shock* comes from the French word “choquer,” meaning “to collide with.” This is particularly appropriate terminology for shock due to sepsis, given our modern understanding of the sepsis pathophysiology, whereby the body's host defenses essentially collide with the invading

microorganism, triggering a profound proinflammatory host response.¹

CONTEMPORARY DEFINITIONS

Shock is defined as a failure of the cardiovascular system to maintain effective tissue perfusion. If effective tissue perfusion is not promptly restored, cellular dysfunction and acute organ failure may occur and may become irreversible, leading to acute organ system failure. When shock develops because of a systemic inflammatory response to infection, it is termed *septic shock*. The American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) first published consensus conference definitions for sepsis syndromes more than 20 years ago,⁵ and these definitions were revisited and further developed by international consensus in 2003.⁶ *Septic shock* was defined as infection-induced hypotension (systolic blood pressure <90 mm Hg [or a drop of >40 mm Hg] plus signs of tissue hypoperfusion despite adequate fluid resuscitation). The concurrent presence of clinical signs of tissue hypoperfusion (e.g., metabolic acidosis, encephalopathy, acute lung injury, oliguria, acute kidney injury, peripheral extremity discoloration, or impaired capillary refill) is an integral component of making the diagnosis of septic shock, because baseline blood pressure can vary among patients, and patients with lower baseline blood pressure may tolerate an arterial pressure lower than the values stated here without being in circulatory shock. The overarching purpose and major impact of the efforts to establish the contemporary definitions given here was the promotion of uniformity in inclusion criteria for sepsis clinical trials.⁷

Figure 23.1 Incidence (cases per 100,000 population) of severe sepsis in the United States compared to four high-profile diseases.⁸⁻¹¹ AIDS, acquired immune deficiency syndrome; VTE, venous thromboembolic disease.

EPIDEMIOLOGY

Severe sepsis (sepsis plus acute organ system dysfunction) is a common and deadly disease with major public health implications. Although heterogeneity of definitions of sepsis has historically made the incidence of severe sepsis and septic shock difficult to precisely measure, estimates of the incidence have been possible. Using the International Classification of Diseases (ICD)-9 codes for infection and organ dysfunction, Angus and coworkers estimated that 751,000 cases of severe sepsis occur in the United States every year.⁸ Figure 23.1 displays the incidence of severe sepsis in the United States compared to other common diseases. The incidence of severe sepsis currently exceeds the incidence of lung and colon cancer, venous thromboembolic disease, and acquired immune deficiency syndrome (AIDS),⁸⁻¹¹ and the incidence is projected to increase by 1.5% per year, resulting in more than 1 million cases of severe sepsis annually by the year 2020.⁸ The incidence of sepsis and septic shock is known to be increasing because of a longer lifespan for patients with severe chronic medical conditions that predispose them to acquiring sepsis. This includes an increase in the number of immunocompromised patients in the community, number of infections caused by resistant organisms, increased use of intravascular catheters, and aging of the population.⁸

Sepsis is the leading cause of death among critically ill patients¹² and is responsible for as many deaths annually in the United States as acute myocardial infarction.⁸ Figure 23.2 displays control arm mortality rates in septic shock clinical trials.¹ In a recent large multicenter registry study, septic patients with both arterial hypotension and severe lactic acidosis experienced a 46% mortality rate, whereas the mortality rate for arterial hypotension or severe lactic acidosis alone was 37% and 30%, respectively.¹³ Overall, severe sepsis in general ranks as the tenth leading cause of death in the United States, with 215,000 deaths annually and an estimated 30% in-hospital mortality rate.^{8,14} Figure 23.3 displays the mortality rate for severe sepsis compared to other high-profile diseases that may require critical care (acute ischemic stroke, acute myocardial infarction, and trauma).^{8,15-17} The apparent disparity in mortality rates across these diseases may be explained in part by differences

Figure 23.2 A compilation of septic shock mortality rates taken from the placebo arms of sepsis clinical trials published over the past decade (listed by first author). (Adapted from Dellinger RP: Cardiovascular management of septic shock. *Crit Care Med* 2003;31(3):946-955.)

Figure 23.3 Mortality rate of severe sepsis in the United States compared to three diseases that are treated aggressively with time-sensitive interventions.^{8,15-17} MI, myocardial infarction.

in the conventional approach to treatment, as acute ischemic stroke, acute myocardial infarction, and trauma are all typically treated with aggressive interventions in a time-sensitive fashion. Similar to the “golden hour” concept for trauma care that was first recognized more than 30 years ago¹⁸ we are now beginning to understand that early aggressive interventions for sepsis can also have an impact on outcome.

It is also important to recognize that, in addition to a high mortality rate, severe sepsis and septic shock are associated with serious risk of morbidity among survivors.^{19,20} A systematic review of the literature found that sepsis survivors had substantially diminished quality of life and a sharply reduced long-term survival after typical short-term (i.e., 28-day) outcomes are assessed.¹⁹ Among older adults, severe sepsis has been associated with major persistent cognitive impairment and functional disability that could have a substantial impact on those patients’ ability to live independently.²⁰ Taken together, even among patients who survive the sepsis insult, the development of severe sepsis or septic shock can represent a pivotal event in the trajectory of a patient’s life.

PATHOGENESIS

Septic shock results when infectious microorganisms in the bloodstream induce a profound inflammatory response causing hemodynamic decompensation. The pathogenesis involves a complex response of cellular activation that triggers the release of a multitude of proinflammatory mediators. This inflammatory response causes activation of leukocytes and endothelial cells, as well as activation of the coagulation system. The excessive inflammatory response that characterizes septic shock is driven primarily by the cytokines tumor necrosis factor- α (TNF- α) and interleukin 1 (IL-1) that are produced by monocytes in response to an infection. Although TNF- α and IL-1 are central to the pathophysiology of septic shock and act synergistically to induce hypotension in experimental models, a number of other vital mediators are also known

to play a major role, including high-mobility group box 1 (HMGB1) protein.²¹ Another important recent advance in our understanding of septic shock pathophysiology has been identification of the close link that exists between the proinflammatory response of septic shock and activation of the coagulation system (e.g., clinical or subclinical disseminated intravascular coagulation [DIC]).²² Although the systemic inflammatory response of sepsis triggers profound macrocirculatory and microcirculatory changes that impair tissue perfusion, another important mechanism playing a role in the development of acute organ dysfunction in septic shock is apoptosis (programmed cell death). Accelerated apoptosis is known to be a critical pathogenic event in this disease. In addition, certain genetic polymorphisms are becoming recognized as major determinants of susceptibility to infection, as well as risk of death from septic shock. Key steps in the pathogenesis of septic shock are shown in Figure 23.4.

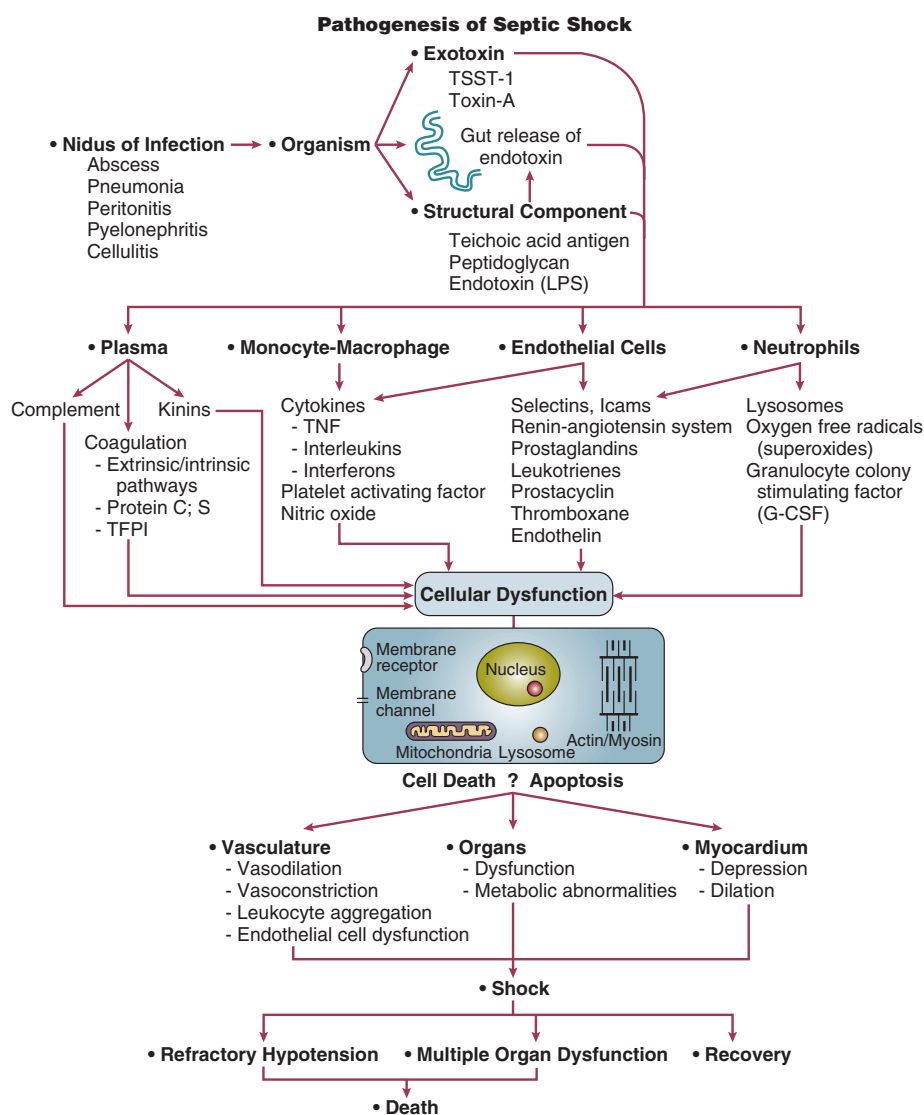

Figure 23.4 Pathogenetic sequence of the events in septic shock. LPS, lipopolysaccharide; TFPI, tissue factor pathway inhibitor; TNF, tumor necrosis factor; Toxin A, *Pseudomonas aeruginosa* toxin A; TSST-1, toxic shock syndrome toxin 1. (Data from Parrillo JE: Pathogenetic mechanisms of septic shock. *N Engl J Med* 1993;328:1471-1477.)

CLINICAL PRESENTATION

Patients with septic shock will typically manifest signs of systemic inflammation including fever or hypothermia, tachycardia, tachypnea, and elevation or reduction of the white blood cell count. Although the absence of arterial hypotension does not necessarily exclude the possibility of subclinical tissue hypoperfusion,²³ the hallmark of septic shock is arterial hypotension despite adequate volume resuscitation requiring vasoactive drugs for hemodynamic support. Other signs of potential tissue hypoperfusion may include lactic acidosis, oliguria, encephalopathy, or diminished capillary refill in the extremities. Patients with septic shock typically have multiple organ system dysfunctions; clinical evidence of other organ system dysfunction may range from subtle abnormalities to overt organ failure. Multiorgan system involvement in sepsis may include cardiovascular, respiratory, renal, central nervous system, hepatic, metabolic, or hematologic dysfunction. Respiratory system dysfunction manifests as acute lung injury or, in the most extreme cases, the acute respiratory distress syndrome (ARDS). Sepsis-induced renal dysfunction typically manifests with oliguria and may progress to acute renal failure requiring dialysis. Central nervous system dysfunction will manifest as encephalopathy, which may range from mild cognitive impairment to overt coma. Cholestasis is a common manifestation of hepatic dysfunction in sepsis, but in the presence of severe shock, ischemic hepatitis (“shock liver”) may occur. Metabolic derangements of septic shock include a loss of glycemic control (hyper- or hypoglycemia) as well as metabolic acidosis. Septic shock is commonly associated with a consumptive coagulopathy, which is likely present in almost all patients at least subclinically,²⁴ but may also manifest clinically with thrombocytopenia, prolongation of the prothrombin time, or in the most severe cases, overt DIC.

The multiple organ dysfunction associated with septic shock is not only a critical event in the pathogenesis of this disease, but is also closely linked with mortality rate.^{8,25,26} There is an approximate 20% increase in septic shock mortality rate with each additional organ system that fails.⁸ Early evidence of organ failure is an especially strong predictor of death.^{26,27} Early improvement in organ function (e.g., 0-24 hour improvement in the Sequential Organ Failure Assessment [SOFA] score^{28,29}) is closely related to sepsis survival, whereas later improvement after the first 24 hours has little predictive value.²⁷ These data, garnered largely from observational studies as well as placebo arms of interventional trials, support the concept that aggressive therapy for sepsis to reverse (or prevent the development of) acute organ system failure within the first 24 hours is closely associated with eventual outcome.

HEMODYNAMIC PROFILE OF SEPTIC SHOCK

The hemodynamic profile of septic shock is the most complex hemodynamic profile of all shock etiologies (Fig. 23.5). What sets septic shock apart from other causes of circulatory shock is the fact that there may be multiple

different mechanisms of circulatory shock occurring simultaneously.^{1,30} Septic shock may have features of (1) hypovolemic shock (poor cardiac filling secondary to severe systemic capillary leak and increased venous capacitance), (2) cardiogenic shock (infection-induced myocardial depression), and (3) distributive shock (arteriolar vasodilation with tissue hypoperfusion in the face of an adequate cardiac output).¹

HYPOVOLEMIA

The release of proinflammatory mediators into the circulation causes injury to the integrity of the endothelial cell surface throughout the systemic microvasculature, resulting in severe capillary leak and extravasation of fluid into tissues. Venodilation also compromises venous return. These are major factors in producing hypovolemia in the patient with septic shock. The septic shock patient may have a markedly decreased cardiac preload, especially in the initial phase of therapy. Aggressive resuscitation with intravenous volume expansion modulates the hemodynamic profile of septic shock and allows the patient to achieve a hyperdynamic (i.e., high cardiac output) state.¹ The combination of a decreased preload and myocardial depression means that in the early phase of sepsis resuscitation, patients may initially be hypodynamic (i.e., low cardiac output) prior to receiving adequate volume resuscitation. Capillary leak is an ongoing process in the course of septic shock therapy, and therefore hypovolemia may recur later in the course of the disease, even after adequate cardiac filling has been initially achieved. Fluid balance (input of intravenous fluids and output of urine) is an unreliable parameter for assessing adequacy of fluid resuscitation in septic shock.

MYOCARDIAL DYSFUNCTION

Septic shock is associated with depression of biventricular function with a decrease in the ejection fraction. Ventricular dilation occurs as a compensatory mechanism and raises end-diastolic volume so that stroke volume can be preserved, taking advantage of the Starling principle. When myocardial dysfunction occurs, a high cardiac output can still be achieved in many circumstances because of biventricular dilation, tachycardia, and arteriolar dilatation, as long as the patient is adequately volume resuscitated and does not have a severe cardiac suppression (related either to previously existing cardiac dysfunction or overwhelming sepsis-induced suppression of cardiac systolic function).³⁰ The most important inflammatory mediators that induce myocardial depression are TNF- α , IL-1, and perhaps nitric oxide.^{31,32} Coronary blood flow is typically normal or increased in septic shock.³³ Although coronary blood flow can be diminished by severe arterial hypotension that compromises coronary perfusion pressure (especially if there is preexisting coronary artery disease), myocardial ischemia does not appear to be the causative factor of the depression in myocardial performance. It has been reported that nearly half of patients with septic shock will have echocardiographic evidence of some degree of depression of systolic function, even in the absence of preexisting cardiac disease.³⁴ However, myocardial depression is typically not the predominant feature of the septic shock hemodynamic profile.³⁰

Figure 23.5 Cardiovascular changes associated with septic shock and the effects of fluid resuscitation. **A**, Normal (baseline) state. **B**, In septic shock, left ventricular blood return is reduced owing to a combination of capillary leak (*inset*), increased venous capacitance (VC), and increased pulmonary vascular resistance. The stroke volume is further compromised by a sepsis-induced decrease in left and right ventricular (RV) contractility. Tachycardia and increased left ventricular compliance serve as countermeasures to combat low cardiac output, the latter by increasing left ventricular preload. However, cardiac output remains low to normal. Finally, a decrease in arteriolar (systemic vascular) resistance allows a higher stroke volume at any given contractility and left ventricular filling state, but also the potential for severe hypotension, despite restoration of adequate left ventricular filling. **C**, Aggressive fluid resuscitation compensates for capillary leak, increased venous capacitance, and increased pulmonary vascular resistance by reestablishing adequate left ventricular blood return. Decreased arteriolar resistance (AR), tachycardia, and increased left ventricular compliance compensate for decreased ejection fraction. Ejection fraction increases as left ventricular filling increases. The net result is that after adequate volume resuscitation, most patients with severe sepsis have a high cardiac output and low systemic vascular resistance state. AO, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; VR, venous return; \rightarrow , blood flow (cardiac output); \Rightarrow , contractility. (From Dellinger RP: Cardiovascular management of septic shock. Crit Care Med 2003;31(3):946-955.)

For the majority of patients, aggressive intravascular volume expansion to restore adequate cardiac filling pressures will be enough to achieve a reasonable cardiac output.

DISTRIBUTIVE SHOCK

Septic shock is characterized by peripheral maldistribution of blood flow to tissues such that tissue hypoperfusion abnormalities can persist despite a normal or high cardiac output. This is called “distributive shock.”³⁰ This maldistribution of blood flow may occur at both microcirculatory and macrocirculatory levels. The role of microcirculatory dysfunction is discussed in detail in the next section of this chapter. At the level of the macrocirculation, the autoregulation of blood flow within any single organ system in a normal host can typically maintain effective tissue perfusion over a wide range of systemic pressures (usually ranging from a mean arterial pressure [MAP] of 50 mm Hg to 150 mm Hg). However, there is heterogeneity of blood flow

distribution throughout the body in septic shock due to preferential shunting of blood flow to vital organs (e.g., the brain and myocardium). The gastrointestinal tract may be the earliest organ system to experience tissue hypoperfusion in septic shock, as blood is shunted away from the splanchnic circulation in order to preserve blood flow to the brain, myocardium, and skeletal muscles. Ischemic injury to the gastrointestinal tract may be a source of ongoing systemic inflammation in septic shock.

The three components of the hemodynamic profile of septic shock are displayed in [Figure 23.6](#).

MICROCIRCULATORY AND MITOCHONDRIAL DYSFUNCTION

After restoration of adequate cardiac filling pressures and achievement of optimal cardiac output in patients with septic shock, tissue dysoxia may still occur via a number of

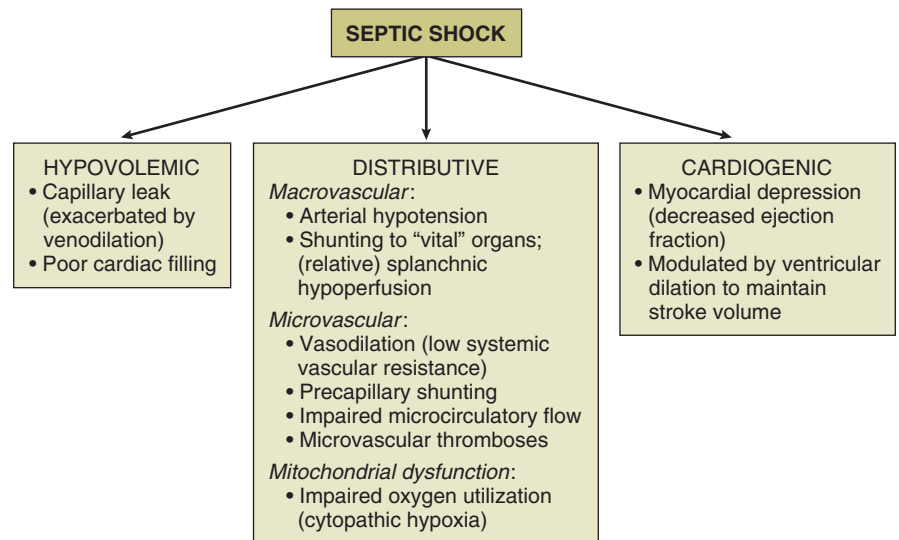

Figure 23.6 Major components of the hemodynamic profile in septic shock. (From Trzeciak S, Parrillo JE: Septic shock. In Society of Critical Care Medicine 8th Adult Critical Care Refresher Course. Chicago, Society of Critical Care Medicine, 2004.)

pathogenic mechanisms. These mechanisms of tissue dysoxia in the face of a normal or a supranormal cardiac output may be due to either (1) microcirculatory dysfunction or (2) mitochondrial dysfunction. These pathogenic mechanisms impair the way in which individual cells can either receive or utilize oxygen, respectively.

MICROCIRCULATORY DYSFUNCTION

Microcirculatory dysfunction is a pivotal element of the pathogenesis of septic shock.³⁵⁻³⁸ Although the macrocirculation (heart and large arteries) regulates the global distribution of blood flow throughout the body, it is the microcirculation that controls the delivery of blood flow to tissues. Using intravital videomicroscopy, experimental models of sepsis have demonstrated impaired microcirculatory flow velocity, “stopped-flow” microvessels, increased heterogeneity of regional perfusion, and low density of perfused capillaries.³⁹⁻⁴² These derangements can cause marked alterations of oxygen transport including impaired tissue oxygen extraction.⁴³ With the advent of new investigational videomicroscopy techniques, it is now possible to study the microcirculatory network in human subjects with septic shock. Microcirculatory failure appears to be one of the critical pathogenic events in sepsis that is associated with acute multiorgan dysfunction and death.³⁵⁻³⁸ As these alterations of microcirculatory flow in sepsis can occur in the *absence* of global hemodynamic perturbations (i.e., absence of low arterial pressure or low cardiac output),^{36,42,44} derangements of small vessel perfusion are largely a function of intrinsic events in the microcirculation.

The causes of microcirculatory flow alterations in sepsis (Fig. 23.7) are multifactorial and include endothelial cell dysfunction, increased leukocyte adhesion, microthrombi formation, rheologic abnormalities, altered local perfusion pressures due to regional redistribution of blood flow, and functional shunting.^{39,45} The proinflammatory cytokines released in sepsis cause diffuse endothelial cell activation, which is associated with neutrophil activation, expression of endothelial adhesion molecules (i.e., integrins and selectins), and localization of white blood cells to areas of

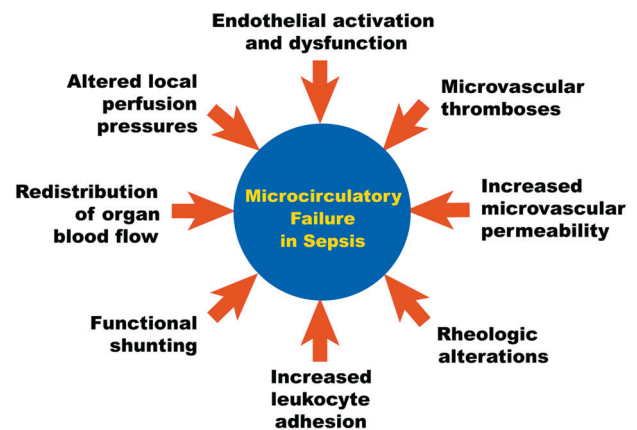

Figure 23.7 Causes of microcirculatory failure in sepsis. (Adapted from Spronk PE, Zandstra DF, Ince C: Bench-to-bedside review: Sepsis is a disease of the microcirculation. Crit Care 2004;8(6):462-468.)

microvascular injury. Pan-endothelial cell injury increases microvascular permeability with the influx of proinflammatory cells into the tissues; this is hypothesized to be an important pathogenic step in the development of acute system organ dysfunction in sepsis. Leukocyte adhesion of white blood cells to the microvessel endothelial surface (primarily in the postcapillary venule) further impedes microcirculatory blood flow. The endothelial injury also triggers the activation of the coagulation cascade via expression of tissue factor on the microvascular endothelium, resulting in fibrin deposition and microvascular thrombosis that may further impair microcirculatory flow. All of these mechanisms collectively contribute to microcirculatory failure in septic shock.^{37,39}

Although septic shock research has classically been focused on macrocirculatory hemodynamic parameters that reflect the distribution of blood flow globally throughout the body, a functional microcirculation is another critical component of the cardiovascular system that is necessary for *effective* blood flow to tissues. This conceptual framework is depicted in Figure 23.8. Although a shift of research focus

Paradigm for Resuscitation of Patients with Tissue Hypoperfusion

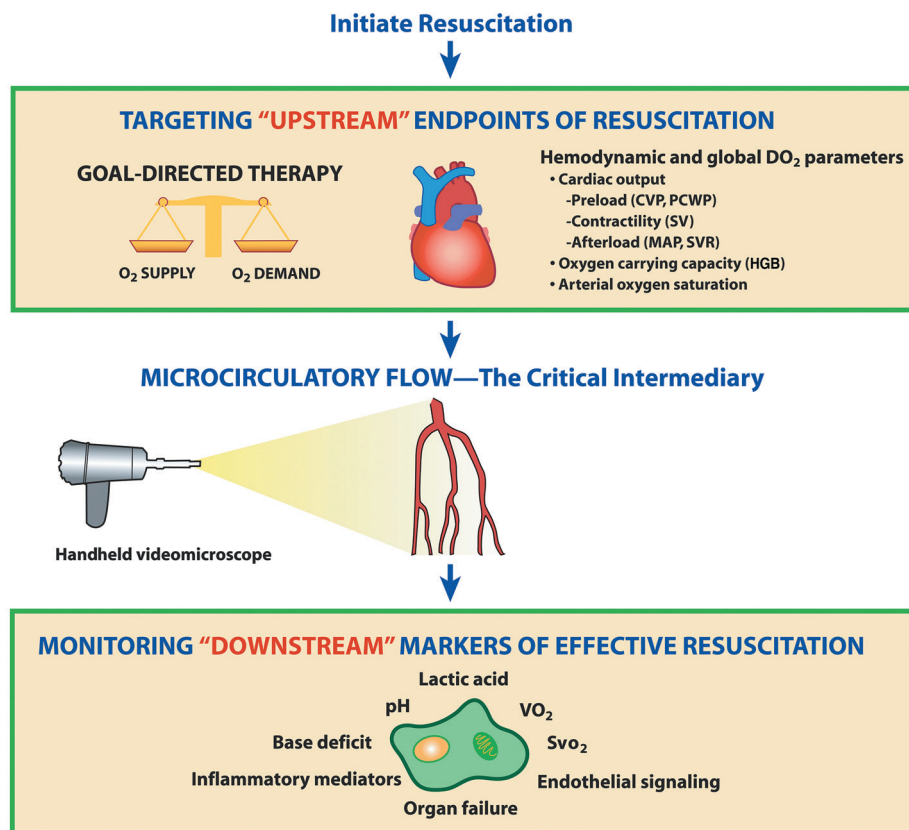

Figure 23.8 New paradigm of the cardiovascular profile of septic shock featuring the importance of the microcirculation. Conventional resuscitation targets the optimization of macrocirculatory (i.e., “upstream”) hemodynamic parameters, with the monitoring of “downstream” surrogates of tissue perfusion to determine the effectiveness of resuscitation. The microcirculation is the critical intermediary. Although the macrocirculation (heart and large arteries) regulates the global distribution of blood flow throughout the body, an intact and functional microcirculation is necessary for the effective delivery of blood flow to tissues. Intrinsic microcirculatory dysfunction can be a pivotal pathogenic event in the development of sepsis-associated tissue hypoperfusion. Using new videomicroscopy techniques, microcirculatory flow can now be studied in human subjects with septic shock. CVP, central venous pressure; DO₂, oxygen delivery; HGB, hemoglobin; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; SV, stroke volume; Svo₂, mixed venous oxygen saturation; SVR, systemic vascular resistance; VO₂, oxygen consumption.

from global hemodynamic parameters to indices of microvascular perfusion could potentially be viewed as a major change of direction for septic shock research, the microcirculation likely represents a logical next frontier in the evolution of our understanding of circulatory failure in shock states.^{37,46} Although there are currently no therapies to specifically target microcirculatory dysfunction in sepsis, going beyond optimization of macrocirculatory hemodynamics and developing new innovative strategies to reverse microcirculatory failure could (in the future) potentially represent a cutting edge method to augment tissue perfusion in sepsis.

MITOCHONDRIAL DYSFUNCTION

There is strong evidence that cellular utilization of oxygen can be markedly impaired in septic shock.⁴⁷ Bioenergetic failure can occur even after effective restoration of blood

flow to tissues has been achieved, and this has been termed “cytopathic hypoxia.” Despite the current absence of therapies to reverse cytopathic hypoxia, this phenomenon does have some relevance for clinical practice, as impaired cellular oxygen extraction and utilization can manifest clinically with acute organ system failure in the setting of markedly elevated values for mixed (or central) venous oxygen saturation. This venous hyperoxia likely reflects bioenergetic failure and identifies a population at exceptionally high risk of death.⁴⁸ Cytopathic hypoxia has been associated with acute organ dysfunction, but the extent to which this does or does not represent a cause-and-effect relationship has not yet been fully elucidated.

Microcirculatory and mitochondrial dysfunction likely coexist in septic shock. Both of these pathogenic mechanisms can impair tissue oxygen delivery and utilization, but the relative contribution of either mechanism is difficult to discern and may vary considerably.

MANAGEMENT OF SEPTIC SHOCK

OVERVIEW AND MANAGEMENT GUIDELINES

The Surviving Sepsis Campaign (SSC) first published comprehensive international consensus guidelines for sepsis management in 2004.^{49,50} The SSC guidelines have been updated over time as the best evidence for sepsis management continues to evolve. The critical care practitioner should be familiar with the concepts in the SSC guidelines and is referred to the most recent update for a comprehensive review including evaluation of the strength of evidence for each recommendation.^{50a} The SSC guidelines writing committee comprised representatives from numerous medical professional societies that relate to the care of the septic patient, and these medical professional societies have endorsed the guidelines.

The treatment recommendations in the SSC guidelines are intended to provide guidance for clinicians. However, treatment decisions must be individualized to the patient, and the recommendations cannot replace a clinician's decision-making capability when he or she is presented with a patient's unique set of clinical data. In addition, resource limitations in some institutions may prevent physicians from accomplishing some treatment recommendations. Thus, the SSC guidelines are intended to represent "best practice" recommendations for the management of sepsis rather than standard of care.

GENERAL PRINCIPLES

The patient with septic shock should be brought to a critical care area as quickly as possible to facilitate rapid resuscitation and optimal hemodynamic support. Continuous electrocardiographic monitoring and pulse oximetry are useful tools in the management of critically ill patients with sepsis.^{51,52} In addition, a variety of more invasive devices may be of use. The arterial catheter has two functions: It allows frequent blood sampling and continuous assessment of arterial pressure. The pulmonary artery catheter (PAC) can provide data such as cardiac filling pressures, cardiac index, and systemic vascular resistance. The data gathered from the PAC can be useful for titrating vasoactive medications in septic shock. Although indications for PAC utilization are controversial and are often debated, it is important to recognize that the PAC represents a tool for guiding therapy rather than being a therapeutic intervention in itself. Monitoring venous oxygen saturation (either mixed venous oxygen saturation [$\text{S}\bar{\text{v}}\text{O}_2$] or central venous oxygen saturation [ScvO_2]) can yield information on the oxygen supply/demand relationship, especially in the early resuscitation phase of septic shock therapy.²³ A markedly low value for either $\text{S}\bar{\text{v}}\text{O}_2$ or ScvO_2 indicates a significant imbalance in the oxygen supply/demand relationship, and likely indicates a need for augmenting global oxygen delivery.

Metabolic parameters to monitor the effectiveness of resuscitation and cardiovascular support are limited; however, measurement of blood lactate can provide important information. In 1964, Weil first proposed the utilization of blood lactate levels as a surrogate of adequacy of tissue perfusion.⁵³ It is important to realize, however, that elevation of blood lactate does not necessarily indicate ineffective

tissue perfusion, as metabolic derangements and altered cellular metabolism may cause hyperlactatemia and can be responsible for the elevation of blood lactate observed in sepsis. Despite this, blood lactate levels still have prognostic value in septic patients. Regardless of the cause of lactate elevation in sepsis, markedly elevated blood lactate (e.g., lactate ≥ 4 mmol/L) signals an increased risk of death.⁵⁴⁻⁵⁸

ANTIBIOTIC THERAPY AND SOURCE CONTROL

Early administration of empiric antibiotic therapy and expeditious source control to eliminate any nidus of infection are imperative in the management of septic shock. Appropriate antibiotics given early may substantially improve the likelihood of survival.^{59,60} A choice of antibiotics is usually empiric because the organism is not yet identified when antibiotics must be delivered. Failure to include antibiotic coverage for what is later identified to be the offending organism has been associated with increased risk of death;⁶¹ therefore, broad-spectrum antibiotics are necessary as soon as septic shock is identified. Kumar and associates performed a large-scale multicenter retrospective study of patients with septic shock and found a linear association between the duration of hypotension prior to first dose of antibiotic administration and risk of death.⁶² One recent prospective emergency department (ED)-based study from Puskarich and colleagues found higher survival rates if antibiotics were administered prior to shock onset compared to after shock onset, but in contrast to the Kumar data the authors did not find a measurable effect of incremental time to administration of antibiotics on survival.⁶³ One potential reason to explain these results is that the Kumar study was a heterogeneous population and the therapeutic interventions (e.g., early resuscitation and hemodynamic support) that the patients received were not standardized, whereas all the patients in the Puskarich study were ED patients treated according to a standardized early resuscitation protocol.

The SSC currently recommends that intravenous antimicrobial therapy be started as soon as possible, preferably within an hour of recognition of septic shock. Even though a 1-hour time window is deemed desirable, the SSC acknowledges that longer time frames are common in real-world clinical practice, and practice surveys verify that a 1-hour window is currently not standard of care.¹³ One reason for this could be the fact that sepsis often mimics other disorders, and the diagnosis of sepsis as the cause of the illness is often not obvious at the time of initial presentation. As such, the need for antimicrobial agents in the treatment of the patient may also not be immediately obvious. Once the diagnosis is made (or strongly suspected), antimicrobial therapy should be started promptly. Initial empiric antimicrobial selection should be broad enough to cover all likely pathogens based on clinical circumstances. In patients with septic shock, de-escalation or restriction of antibiotic therapy as a strategy to reduce the development of antimicrobial resistance is not recommended until after a causative organism has been identified or after the patient's condition has markedly improved.

Pertaining to source control, the SSC recommends that a specific anatomic diagnosis of infection requiring

consideration for emergent source control (e.g., laparotomy for intra-abdominal source) be sought and diagnosed or excluded as rapidly as possible. Thus, imaging studies, if needed, should be performed as soon as possible to make the diagnosis. One important caveat to this is the inherent hemodynamic instability and overall severity of illness in septic shock that may make invasive procedures or transport of patients outside the intensive care unit for imaging studies potentially unsafe. Balancing potential risks and benefits in that scenario is very important. When a procedure for source control is found to be necessary, the surgical drainage should be undertaken for source control as soon as feasible following successful initial resuscitation. Specifically, the SSC recommends that this occur within the first 12 hours after the diagnosis is made. One exception to this may be necrotizing pancreatitis with suspected infection, for which a delayed approach to surgical management (i.e., intravenous antimicrobial therapy only at first, in addition to supportive care) may be preferred.

EARLY RESUSCITATION

One of the initial goals in the early management of a patient with septic shock is effective resuscitation to restore adequate tissue perfusion and decrease the risk of organ system injury. A number of hypotheses have been developed to explain the relationship between shock and the development of organ failure in critical illness. One hypothesis suggests that organ failure during critical care occurs as a consequence of inadequate oxygen delivery. Based on this hypothesis, a number of investigators have suggested that patients should be resuscitated to supranormal goals of systemic oxygen delivery in an attempt to prevent organ failure and improve outcome. The concept of supranormal oxygen delivery refers to the use of fluid resuscitation and inotropic drugs to drive up the oxygen delivery to achieve a predefined target. Several studies have examined this concept, although it is important to recognize that some studies have been performed in heterogeneous populations of critically ill patients rather than sepsis populations. The earliest clinical trials in perioperative high-risk surgery patients demonstrated an outcome benefit.^{64,65} Subsequently, however, numerous trials of supranormal oxygen delivery in critically ill patients failed to demonstrate any benefit. In the largest of these studies, Gattinoni and coworkers found no difference in survival or organ failure in a large number of critically ill patients when comparing patients resuscitated to supranormal end points to those receiving standard care.⁶⁶ In a study by Hayes and associates, increasing oxygen delivery to supranormal levels with the use of high-dose dobutamine was associated with a reduction in survival.⁶⁷ A meta-analysis concluded that supranormal oxygen delivery in critically ill patients was not beneficial⁶⁸ and this concept largely fell out of favor in the 1990s.

For goal-oriented hemodynamic optimization to be beneficial, it has become clear that *timing* is critical. In contrast to the trials in perioperative high-risk surgery patients, subjects in the Gattinoni study were randomized much later, up to 72 hours after initial presentation.⁶⁶ In a meta-analysis of critically ill patients that stratified studies by severity and the timing of interventions (early versus late), an outcome benefit was identified in the subset of patients with a high

severity of illness and early initiation of interventions.⁶⁹ A recent meta-analysis, this time specifically focused on patients with sepsis, found that quantitative resuscitation (i.e., early hemodynamic optimization targeting predefined quantitative end points of resuscitation) was associated with lower mortality rate in sepsis patients, but only if applied early, defined as less than 24 hours after presentation.⁷⁰ These data suggest that quantitative resuscitation in the treatment of severe sepsis and septic shock can in fact be beneficial—in the right patient.

This early intervention concept was the rationale behind the study of early goal-directed therapy (EGDT) for severe sepsis and septic shock by Rivers and colleagues.²³ EGDT is a type of quantitative resuscitation for septic patients that involves targeting central venous oxygen saturation (ScvO₂) as a monitor of the adequacy of oxygen delivery. In a single-center randomized controlled trial of 263 ED patients with severe sepsis and septic shock, Rivers and colleagues targeted predefined end points of resuscitation including central venous pressure (CVP) 8 to 12 mm Hg, MAP 65 mm Hg or greater, and ScvO₂ 70% or greater in the ED. The authors reported that the EGDT protocol was associated with a 16% absolute risk reduction for mortality rate (30.5% vs. 46.5%). This study was an important contribution to the literature in showing that early interventions in the resuscitation phase of therapy can be associated with a significant improvement in long-term survival for patients with sepsis.

Recently, a multicenter ED-based randomized trial from Jones and associates compared lactate clearance (defined as a decrease by $\geq 10\%$ in the serum lactate concentration) versus ScvO₂ as an end point of sepsis resuscitation.⁷¹ Among 300 patients with sepsis-induced tissue hypoperfusion, the authors found that lactate clearance was noninferior to ScvO₂ for the primary outcome of all-cause in-hospital deaths. These data suggest that, in addition to ensuring adequate cardiac preload and arterial blood pressure, lactate clearance has potential as a resuscitation target in sepsis-induced tissue hypoperfusion.

The data are conflicting as to what therapeutic interventions are typically needed beyond intravascular volume expansion and vasopressor agents in the early resuscitation of patients with sepsis. In the Jones trial, after aggressive administration of intravenous crystalloid to achieve a CVP of 8 to 12 mm Hg and vasopressor agents to achieve an arterial pressure of 65 mm Hg or greater in a stepwise resuscitation algorithm, very few patients required additional therapies for augmentation of oxygen delivery to achieve either lactate clearance or ScvO₂ goals (i.e., only 7% required packed red blood cell transfusion and 3% required inotropes). In contrast, 64% of patients in the EGDT (ScvO₂ targeted) arm in the Rivers study were treated with blood transfusions and 14% were treated with inotropic support. The Rivers data would suggest that packed red blood cell transfusions and inotropes are commonly required therapies for optimization of oxygen delivery in sepsis resuscitation, whereas the Jones trial (and multiple other recent observational clinical studies) suggests that these additional therapies are rarely required to achieve resuscitation goals. Although the optimal end points of quantitative resuscitation for sepsis remain controversial, it is generally accepted that the earlier the therapeutic interventions are delivered,

the greater the capacity for benefit. Therefore, the resuscitation phase of therapy appears to be an important window of opportunity for impact on outcome.

Currently, the SSC recommends the following end points for quantitative resuscitation: CVP 8 to 12 mm Hg, MAP 65 mm Hg or greater, urine output 0.5 mL/kg/hour or greater, and $ScvO_2$ 70% or greater (or mixed venous oxygen saturation [$S\bar{v}O_2$] $\geq 65\%$). Although arterial pressure and urine output are routinely monitored in critical care practice, targeting CVP and central or mixed venous oxygen saturation necessitates invasive hemodynamic monitoring. If invasive hemodynamic monitoring is not yet in place (or is not established for any reason), aggressive empiric resuscitation should still be performed because it is possible that empiric resuscitation can optimize cardiac filling pressure and oxygen delivery even if the specific values for CVP or central/mixed venous oxygen saturation are not recorded. The SSC also recommends targeting resuscitation to lactate normalization as soon as possible in patients with elevated serum lactate levels, especially if $ScvO_2$ values are not available. Targeting both $ScvO_2$ at 70% or greater and lactate normalization as a combined end point is also an option if both are available.

The SSC acknowledges limitations with utilizing static ventricular pressure estimates (e.g., CVP) for assessing intravascular volume status in septic shock patients. Specifically, measuring CVP in a range that is typically thought to be normal (or even high) does not necessarily exclude the possibility of preload-dependent cardiac output, especially in patients with preexisting chronically elevated cardiac filling pressures (e.g., cardiomyopathy or pulmonary artery hypertension). However, a markedly low value for CVP can be helpful in that it can reliably indicate the presence of hypovolemia in patients with circulatory shock. Targeting dynamic measures of fluid responsiveness during resuscitation and perhaps volumetric indices (e.g., pulse pressure variation, stroke volume variation) may eventually prove to be advantageous, but these newer techniques of intravascular volume assessment have not yet been widely adopted in practice and require future research.

The SSC also acknowledges that achievement of quantitative resuscitation goals can be challenging in routine clinical practice. Although some centers have been successful in implementing programs for quantitative resuscitation,⁷² a recent large multicenter observational study of the translation of SSC recommendations to clinical practice found that clinicians currently achieve all recommended end points of resuscitation less than 50% of the time.¹³ The reasons for this are likely multifactorial but may include the fact that from a practical standpoint the provision of quantitative resuscitation at the bedside can be relatively resource intensive, and some institutions may not have the necessary infrastructure to provide this service consistently at the present time.

CARDIOVASCULAR SUPPORT

The main goal of cardiovascular support in septic shock is to use intravascular volume expansion and vasoactive agents to help restore and maintain effective tissue perfusion. The main components of cardiovascular support in septic shock can be grouped into three separate and distinct categories:

volume resuscitation, vasopressor therapy, and inotropic support. The goal of volume resuscitation is to optimize cardiac filling in order to augment cardiac output. Although many vasoactive drugs have both vasopressor and inotropic activity, this distinction is made on the basis of intended goals of therapy. Vasopressor activity primarily raises the arterial pressure, whereas inotropic activity augments myocardial contractility and raises cardiac output.

VOLUME RESUSCITATION

Aggressive intravascular volume expansion is another cornerstone of septic shock management and is the best initial therapy for the cardiovascular instability of sepsis. The initial hypotension observed in many patients with sepsis-induced cardiovascular instability may be reversed with volume infusion alone. A reasonable approach to initial volume resuscitation in the adult patient is the rapid administration of 2 to 3 L of crystalloid solution (e.g., 0.9% NaCl or lactated Ringer's solution). If (after initial volume infusion) the hemodynamic instability has resolved, further aggressive resuscitation may be unnecessary and the patient may be relegated to a somewhat higher maintenance fluid.

Because there is no proven benefit of colloid therapy over crystalloids in resuscitation,⁷³ the SSC currently recommends initiating volume resuscitation with crystalloid for patients with septic shock and suspicion of hypovolemia. The SSC-recommended volume of crystalloid is a minimum of 30 mL/kg fluid challenge. If there is hemodynamic improvement with this initial fluid challenge, clinicians may continue repeated fluid challenges to see if further hemodynamic improvement occurs. The SSC further suggests consideration of the addition of albumin infusion to initial crystalloid resuscitation if the initial crystalloids are judged to be ineffective. The SSC recommends against the use of synthetic hydroxyethyl starches in volume resuscitation because these agents have been associated with increased risk of acute kidney injury.

If a PAC is in place, the target for pulmonary capillary wedge pressure in a patient without preexisting cardiopulmonary disease is likely in the range of 12 to 15 mm Hg;⁷⁴ however, it is imperative to remember that the "optimal" cardiac filling pressure may vary widely from patient to patient. One prudent strategy of volume resuscitation (rather than targeting a predefined cardiac filling pressure) would be to continue fluid bolus administration until the cardiac index fails to rise with additional intravascular volume expansion, indicating optimization of cardiac preload. An extremely high left ventricular filling pressure should be avoided because it could contribute to pulmonary capillary leak and cause impairment of oxygenation if the patient has concomitant acute lung injury. In the absence of a PAC to guide therapy, and if a patient has persistent hypotension refractory to an initial 30 mL/kg crystalloid intravascular volume infusion, it would be prudent to continue administering fluid boluses in attempts to raise the arterial pressure (unless the patient is manifesting clinical signs that pulmonary edema is developing, [e.g., increasing supplemental oxygen requirement]).⁷⁵ Decisions on aggressiveness of fluid resuscitation should be made with consideration of oxygenation status. Patients with minimal supplemental oxygen requirements can be

more aggressively fluid resuscitated with minimal concern for deleterious effects of intravascular volume expansion, but more cautious fluid administration is required in patients requiring higher FIO_2 to maintain adequate oxygenation. Because the intravascular volume that optimizes stroke volume may produce worsening of oxygenation in patients with acute lung injury, intubation and mechanical ventilation may be required in order to assure adequate tissue perfusion.

VASOPRESSOR THERAPY

In addition to fluid administration, pharmacologic support of blood pressure is frequently necessary in both the initial resuscitation and subsequent support of patients with septic shock. These agents are, after fluids, the next most important interventions for the initial management of the hemodynamically unstable patient. Restoration of adequate arterial pressure is the end point of vasopressor therapy. The SSC recommends targeting a MAP of 65 mm Hg; however, blood pressure does not always equate to systemic blood flow, and the precise MAP to target may not necessarily be the same for all patients. LeDoux, Astiz, and coworkers demonstrated that, in septic shock patients treated with norepinephrine to maintain target MAP, MAPs of 65, 75, and 85 mm Hg achieved equivalent indices of tissue perfusion.⁷⁶ In an observational study of patients with septic shock Varpula and associates found that an area under the curve of 65 mm Hg was the best predictor of positive outcome and showed that among multiple hemodynamic variables, a MAP above 65 mm Hg was the best predictor of a favorable outcome.⁷⁷ It is notable that a MAP of 65 mm Hg may be inadequate for a patient with preexisting poorly controlled essential hypertension and associated vascular disease. Similarly, it should be recognized that in some patients it is possible to have arterial pressures lower than 65 mm Hg without tissue hypoperfusion. It is hypotension in the presence of tissue hypoperfusion that merits therapy with vasopressor agents. End points of resuscitation such as arterial pressure should be combined with assessment of regional and global perfusion. Other bedside indicators of persistent tissue hypoperfusion (besides hypotension) include oliguria, encephalopathy, poor capillary refill, and metabolic acidosis. Thus, even though the SSC recommends targeting a MAP of 65 mm Hg for most patients, the optimal MAP should be individualized based on the clinical considerations noted here.

The appropriate use of vasopressors may require accurate assessment of a patient's cardiovascular status with invasive hemodynamic monitoring. However, in the earliest stage of therapy, it is common to institute vasopressor therapy when invasive monitoring data is not immediately available if a patient remains hypotensive despite adequate intravascular volume expansion. If the MAP remains low (e.g., <65 mm Hg) with evidence of ongoing tissue hypoperfusion despite adequate fluid resuscitation, vasopressor therapy is indicated. In some circumstances, patients with sepsis may require vasopressor support even if hypovolemia has not yet been resolved. Below a threshold blood pressure, autoregulation of blood flow in vascular beds may be lost and linearly dependent on blood pressure; thus the administration of vasopressor agents to achieve a minimal perfusion pressure and maintain adequate flow is reasonable as an emergency measure in some situations while fluid resuscitation is ongoing.

INDIVIDUAL VASOACTIVE AGENTS

Multiple different vasoactive agents including norepinephrine, epinephrine, vasopressin, dopamine, and phenylephrine can achieve arterial pressure goals in the management of patients with septic shock. The different catecholamine agents have different effects on α - and β -adrenergic receptors. The hemodynamic actions of these receptors is well described: α -adrenergic receptors promote vasoconstriction, but β_1 -adrenergic receptors increase heart rate and myocardial contractility and β_2 -adrenergic receptors cause peripheral vasodilation. Given the differential effects of vasopressor drugs upon adrenergic receptors, these different agents have different effects upon arterial pressure and systemic blood flow. In this context, the quintessential question as to which catecholamine is the best initial choice for treating septic shock is best framed as a question of which agent is most appropriate for a given therapeutic strategy in an individual patient, and is largely dependent upon that individual patient's hemodynamic status. Rather than a "one size fits all" strategy, vasoactive agents should be carefully selected based on the intended goals of therapy.

Vasoactive agents and their characteristics are summarized in Table 23.1. The selection of one of these drugs over the other as a first-line agent is a controversial and an often debated subject in the field of critical care medicine. Both norepinephrine and dopamine will effectively raise the

Table 23.1 Vasoactive Agents Commonly Used for Hemodynamic Support in Sepsis

Agent	Typical Dose	Chronotropic Effects	Inotropic Effects	Vasoconstriction
Dopamine	6-20 $\mu\text{g/kg/min}$	++	++	+/++ (dose-dependent)
Epinephrine	1-10 $\mu\text{g/min}$	++	++	++
Norepinephrine	2-30 $\mu\text{g/min}$	+	+	++
Phenylephrine	20-200 $\mu\text{g/min}$	–	–	++
Vasopressin	0.01-0.03 U/min	–	–	++
Dobutamine	2-15 $\mu\text{g/kg/min}$	++	++	–

blood pressure and the cardiac index, but the rise in cardiac index will be greater with dopamine. Dopamine, however, may cause or exacerbate tachycardia or dysrhythmias.⁷⁸ Norepinephrine is a more potent drug than dopamine in achieving a target MAP.¹ Information from five randomized trials ($n = 1993$ patients with septic shock) comparing norepinephrine and dopamine does not support the routine use of dopamine in the management of septic shock.⁷⁹

Epinephrine is a potent α - and β -adrenergic agent that increases MAP by vasoconstriction and also increases the cardiac index. Although epinephrine is a potent agent in raising the arterial pressure, the chief concern with the use of epinephrine has been the potential for impaired splanchnic perfusion.⁸⁰⁻⁸² A large-scale randomized controlled trial comparing epinephrine to norepinephrine plus dobutamine reported no difference in vasopressor withdrawal, organ failure, and mortality rate. There was also no difference in the rates of serious adverse events. The authors concluded that there is no difference in efficacy and safety for epinephrine versus norepinephrine plus dobutamine in the management of septic shock.⁸³

Vasopressin is an agent that has both vasoconstriction and antidiuretic properties. Vasopressin constricts vascular smooth muscle directly via V_1 receptors, and may also increase the responsiveness of the vasculature to endogenous or exogenous catecholamines.^{84,85} Normally, endogenous vasopressin levels are very low, and there is essentially no vasoconstriction effect in a normal host. However, in septic shock vasopressin levels are initially extremely elevated. In prolonged septic shock, a relative vasopressin deficiency can develop. It has been postulated that this relative vasopressin deficiency may be the result of the depletion of the pituitary stores or the downregulation of vasopressin production by the pituitary via the effects of nitric oxide.⁸⁴ Exogenous administration of low-dose vasopressin can have a dramatic hemodynamic response in this scenario, rapidly restoring arterial pressure.^{86,87} A large randomized clinical trial compared vasopressin to norepinephrine in 776 subjects with vasopressor-dependent septic shock. Patients were randomized to vasopressin (0.03 U/minute) or norepinephrine (15 μ g/minute). For the group as a whole (intent-to-treat analysis) there was no difference in the primary end point of 28-day mortality rate. It appears that vasopressin (up to 0.03 U/minute) may be equally safe and effective as norepinephrine in patients with septic shock after fluid resuscitation.⁸⁸ Doses of vasopressin higher than 0.04 U/minute are not recommended due to concerns of coronary, digital, and mesenteric ischemia.

Phenylephrine is a pure vasoconstrictor with α -adrenergic effects alone. Although one potential advantage of using phenylephrine is that it will not cause or exacerbate tachycardia, the increase in peripheral resistance may produce a deleterious lowering of cardiac output. Phenylephrine may be useful in select patients with severe dysrhythmias associated with catecholamine infusion because it has no β -adrenergic effects, as well as in patients with refractory hypotension in the presence of a known high cardiac index.

The SSC recommends norepinephrine as the first-line vasopressor agent in septic shock. The SSC further recommends the addition of either epinephrine or vasopressin (0.03 U/minute) if a second vasopressor agent is needed to support the blood pressure.

INOTROPIC SUPPORT

Inotropic support may be required for patients with septic shock. In the context of severe sepsis-induced myocardial depression, or if the patient has severe preexisting myocardial dysfunction, an inotrope may be necessary to augment cardiac output (typically in combination with a drug that is supporting the MAP). The SSC recommends that dobutamine be the inotrope selected. When used beyond early quantitative resuscitation (first 6 hours of therapy) inotropic therapy is guided by measurements of cardiac index. A reasonable goal for inotropic therapy would be a cardiac index of 3.0 L/minute/ m^2 or greater.

CORTICOSTEROIDS

Administering high doses of steroids (30 mg/kg of methylprednisolone) failed to show an outcome benefit in septic shock in large-scale randomized controlled trials in the 1980s.^{89,90} These studies used large doses of steroids over a short time period in an attempt to blunt the proinflammatory response of sepsis. In contrast, an alternative strategy of administering low-dose (i.e., “stress” or “physiologic” dose) steroids appeared to be promising in multiple small studies in the 1990s.^{91,92} Despite the fact that septic shock patients typically have elevated serum cortisol levels, it was identified that some patients with septic shock may have “relative adrenal insufficiency,” as evidenced by failure to mount a significant elevation of serum cortisol in response to intravenous adrenocorticotrophic hormone (ACTH) stimulation. Relative adrenal insufficiency in the context of septic shock may predispose a patient to persistent cardiovascular failure that is refractory to conventional hemodynamic support therapies, and administration of exogenous low-dose steroids could help achieve shock reversal. On the other hand, administration of exogenous steroids could be associated with deleterious effects such as immunosuppression or myopathy.

In 2000, Annane and colleagues performed an observational study focusing on the ability to respond to an ACTH stimulation test in septic shock.⁹³ The highest 28-day mortality rate (75%) was observed in patients who did not increase serum cortisol level greater than 9 μ g/dL. Being a “nonresponder” was a better predictor of death than an initially low cortisol value. In a randomized controlled trial by the same investigators in 2002, 300 severely ill (persistent hypotension despite fluid resuscitation and vasopressor initiation) septic shock patients were randomized to 7 days of hydrocortisone plus fludrocortisone versus placebo.⁹⁴ The study found that in the 229 nonresponders administration of low-dose steroids was associated with an improvement in time to shock reversal and mortality rate. Patients who responded appropriately to ACTH stimulation test did not demonstrate a benefit with low-dose steroids.

The concept of low-dose steroid administration was further tested in a multicenter randomized controlled trial (CORTICUS).⁹⁵ This study found no difference in the primary outcome measure of mortality rate between those treated with steroids compared to placebo. However, it is notable that (1) in contrast to the Annane study in which all subjects had vasopressor-refractory septic shock, the CORTICUS study tested a more diverse patient population

with overall lower severity sepsis, and (2) randomization in the Annane study occurred within 8 hours of developing shock as opposed to CORTICUS, which randomized subjects up to 72 hours after shock onset. Despite the fact that low-dose steroids do not appear to improve outcome in diverse, less severely ill populations of patients with sepsis, patients with vasopressor-unresponsive septic shock likely benefit. In summary, although steroid therapy should not be used in all patients with septic shock, it could be considered in those with persistent circulatory shock despite the administration of vasopressor agents.

The SSC recommends that intravenous hydrocortisone not be administered to septic shock patients if fluid resuscitation and vasopressor agents can restore an adequate arterial pressure. If arterial pressure cannot be successfully restored and maintained, the SSC suggests intravenous hydrocortisone at a maximum dose of 200 mg per day. The SSC does not recommend the use of an ACTH stimulation test to identify candidates for steroid therapy, but rather using bedside clinical criteria such as the presence of vasopressor-refractory shock. The SSC does not recommend the addition of fludrocortisone to hydrocortisone when steroids are administered. Hydrocortisone should be tapered off when vasopressor agents are no longer required.

SUMMARY

Successful management of the patient with septic shock continues to be a major clinical and public health challenge, as evidenced by persistently high mortality rates associated with this disease. The principal goals of sepsis therapy remain early identification, early empiric antibiotic therapy and infection source control, aggressive resuscitation, and effective cardiovascular support. The hemodynamic profile of septic shock is the most complex of all shock profiles and may be characterized by simultaneous hypovolemia, myocardial depression, and peripheral vascular dysfunction. Clinicians should define goals and end points of hemodynamic support in individual patients, titrate therapies to those end points, and evaluate the effectiveness of their interventions based on improving indices of tissue perfusion.

KEY POINTS

- Septic shock is a clinical syndrome resulting from a systemic infection that triggers an excessive inflammatory response and produces cardiovascular instability.

KEY POINTS (Continued)

- The initial management of the patient with septic shock is aggressive resuscitation and cardiovascular support, as well as early empiric administration of broad-spectrum antibiotics.
- Initial cardiovascular support is achieved with aggressive intravascular volume expansion.
- Vasopressors are administered to patients who remain hypotensive despite fluid administration. Although the selection of vasopressors must be individualized, norepinephrine is typically considered a first-line agent.
- End points of resuscitation should be physiologic values that reflect adequacy of regional and global perfusion. Clinicians should define goals and end points of hemodynamic support, titrate therapies to those end points, and evaluate the results of their interventions on improving indices of tissue perfusion.

MANAGEMENT

FUNDAMENTALS OF TAMPONADE

Cardiac tamponade is a condition characterized by an increase in pressure external to the heart resulting in impaired filling of the cardiac chambers. In the typical scenario, as fluid in the pericardium accumulates, cardiac output falls. The diagnosis represents a continuum from mild tamponade with subtle diagnostic findings to a critical clinical setting with imminent mortality.¹ The variability in presentation, including diagnostic findings and course, and the morbidity and mortality associated with treatment make this a particularly challenging clinical problem in critical care medicine.

PERICARDIAL ANATOMY

The pericardium consists of a visceral and a parietal pericardial segment, the former being composed of a single layer of cells that adhere to the cardiac epicardial surface.^{2,3} The parietal pericardium is the structure responsible for the clinically relevant features of tamponade; it is a relatively noncompliant structure composed of collagen and elastin and normally is less than 2 mm thick. The mechanical properties of the pericardium—in particular, those reflected by its pressure-volume curve (Fig. 24.1)—are responsible for the clinical features seen in cardiac tamponade.

The pericardium extends from the lower third of the superior vena cava to the apex of the heart. It is attached to the sternum, the diaphragm, and the great vessels. Because it extends beyond the heart border, trauma to not only the

heart but also the great vessels approaching the heart borders can lead to cardiac tamponade.⁴

PHYSIOLOGY

Cardiac tamponade is a result of decreased transmural pressure, typically from the accumulation of fluid in the pericardial space (Fig. 24.2). Other causes of “tamponade-like physiology” are related to extrinsic compression of the heart,⁵ although these pathologic processes should be separated from those causing constriction rather than true tamponade. Differentiating these two distinct physiologic entities, constriction and tamponade, is essential to diagnosis and management.

The fluid accumulating in the pericardial space can be blood, serous fluid, purulent material, clot, or rarely gas. As fluid accumulates, the pericardium stretches, until it reaches a point (see Fig. 24.1) at which its degree of compliance is exhausted, so that it has become largely inelastic. At this point, any further increase in intrapericardial fluid is associated with a decrease in intracardiac chamber volume, because the total volume of pericardial fluid, heart muscle, and the cardiac chambers becomes fixed by pericardium no longer able to stretch. This in turn results in decreased filling of the heart and consequently decreased stroke volume. To maintain cardiac output, an early compensatory mechanism is an increase in heart rate. Subsequent adaptations to maintain blood flow to central end organs (heart, brain, kidneys) are venous pressure rise, peripheral vasoconstriction, increase in ejection fraction, and selective shunting of blood to preserve flow to the essential end

Figure 24.1 Pressure-volume curves for normal pericardium on the *left* and compliant pericardium on the *right*. In the setting of rapid onset of effusion in the normal pericardium, low volumes, typically starting from less than 50 mL, lead to a rise in pressure that exceeds the limit of pericardial stretch, with early onset of tamponade physiology. With more compliant pericardium, a result of chronic stretching, critical extramural pressures do not result until substantially higher volumes are achieved, in some cases more than 1 L.

Figure 24.2 The pericardium surrounding the heart in a normal physiologic setting and in tamponade. The pericardium can be seen to extend to the proximal great vessels. Note the large amount of effusion in the image on the *right*, consistent with chronic pericardial stretch, which leads more slowly to tamponade. (From Holmes DR Jr, Nishimura R, Fountain R, Turi ZG. Iatrogenic pericardial effusion and tamponade in the percutaneous intracardiac intervention era. *JACC Cardiovasc Interv* 2009;2(8):705-717.)

organs. Venous pressure increase is accomplished by fluid retention and peripheral venoconstriction. In severe tamponade, equalization of right atrial, right ventricular diastolic, pulmonary diastolic, pulmonary artery wedge, and intrapericardial pressures occurs. Both pulmonary and systemic arterial and pulse pressures fall. Tamponade is a continuum, ranging from a primarily echocardiographic finding of right-sided chamber collapse to shock and pulseless electrical activity.

PERICARDIAL PRESSURE

The normal pericardium contains a small amount of fluid, typically in a range of 20 to 50 mL, resulting in no more than 5 mm of separation between the visceral and the parietal pericardial surfaces. Pressure in the normal pericardium reflects intrathoracic pressure, which in turn reflects

atmospheric pressure, with variation influenced by respiration. During inspiration, the pressure falls a few millimeters below atmospheric pressure (by convention, 0 mm Hg); during expiration, it falls a few millimeters above. The difference between intracardiac and intrapericardial pressures, the transmural pressure, in turn distends or compresses the cardiac chambers. Because intrapericardial mean pressure in patients breathing unassisted typically is the same as atmospheric pressure, whereas right atrial pressure is normally in the range of 2 to 8 mm Hg, the latter is the typical range of net right atrial transmural pressure. When intrapericardial pressure rises to the level of right atrial pressure, the right atrium collapses, a typical feature of early cardiac tamponade, though this nonspecific finding can be seen with hypovolemia alone.

The normal parietal pericardium, because of its limited compliance, limits abrupt expansion of the heart as a whole.⁶ Thus, in the setting of right ventricular infarction, for example, acute dilation of the right ventricle is at the cost of left ventricular volume decrease—a ventricular interdependence phenomenon similar to that illustrated in [Figure 24.3](#). Acute chamber enlargement resulting from other etiologic conditions or disorders, such as abrupt volume loading or sudden onset of severe valvular regurgitation, is impeded by the constraint of pericardium that has reached the limits of its intrinsic elasticity. Because right-sided heart filling occurs preferentially with inspiration, when negative intrathoracic pressures result in increased venous return and higher right-sided chamber volume, left ventricular stroke volume and hence systolic blood pressure tend to fall as left atrial and left ventricular volumes decrease. This exaggerates the normal respiratory variation, and systemic pressure falls with inspiration to a level at which pulsus paradoxus, defined by convention as a greater than 10 mm Hg decrease in systolic pressure, is seen. In addition, decreased intrathoracic pressure has a disproportionate effect on the pulmonary venous circulation, which is not exposed to the high pericardial pressures; hence, a disproportionate fall during inspiration in the pulmonary vein to left atrial gradient further exacerbates the decrease in left atrial filling.⁷ The fall in systolic pressure is not in fact a paradox but rather an exaggeration of normal respiratory variation of approximately 3%⁸ with associated inspiratory decrease in left ventricular stroke volume. With severe tamponade, total elimination of pulse pressure can be seen with individual heartbeats, as in the example in [Figure 24.4](#).

The inability to dilate further means that additional volume beyond the intrinsic stretch limit of the pericardium, such as from bleeding into the pericardial sac, results in increasing compression of heart chambers as volume expands in the pericardial space. Because the right-sided chambers have the lowest intracardiac pressures, in particular the right atrium, those are the first chambers showing collapse, in particular in diastole, when the tricuspid valve is open and the right atrium can decompress into the right ventricle. With a progressive increase in intrapericardial pressure, compression of the right ventricle in diastole occurs during pressure equalization with the right atrium. Eventually, as intrapericardial pressure continues to rise, compression of the left-sided chambers ensues.

In contrast with acute tamponade physiology, in which hemodynamic decompensation may occur after only a

Figure 24.3 Hemodynamic tracings from a patient with ventricular interdependence (200-mm Hg scale). With inspiration, left ventricle (LV) systolic pressure falls as right ventricle (RV) systolic pressure increases. Because of ventricular interdependence, the right ventricular and left ventricular systolic pressures trend in opposite directions (lines connecting peak systolic pressures diverge during phases of the respiratory cycle). Diastolic pressures in both ventricles are essentially identical (*green oval*). Absence of pulsus paradoxus and preserved systolic pressure make this physiology consistent with constriction rather than tamponade. The patient had a clot in the pericardial space after prior cardiac trauma.

modest accumulation of fluid, generally in the range of 100 to 200 mL, chronic pericardial effusion results in a gradual increase in distensibility of the pericardium. With increasing compliance, large amounts of fluid can accumulate at low pressure without decreasing transmural pressure or compressing the cardiac chambers (see Fig. 24.1). Even in chronic low pressure–high volume tamponade, a limit of distensibility is eventually reached that results in similar pathophysiology as with acute tamponade, in some cases only after a liter or more of fluid has accumulated. Once the steep portion of the pressure-volume curve is reached, it is important to appreciate that with accumulation of another 50 to 100 mL of pericardial fluid, hemodynamic decompensation can occur rapidly, with similar outcomes as in patients who suffer from acute tamponade, such as is seen with penetrating trauma, coronary artery perforation, aortic dissection, or cardiac rupture.

ETIOLOGY

Pericardial effusions generally can be characterized as transudate or exudate, infectious or bloody, with tamponade occurring with variable frequency depending both on the rapidity of fluid accumulation and, to a somewhat lesser

degree, on characteristics of the effusion and physiology determined by its etiology. Transudates are characteristic of congestive heart failure, radiation, and uremia; exudates are characteristic of infections, malignancy, and connective tissue disorders. Laboratory testing may help differentiate exudates from transudates; pericardial and serum protein, albumin, lactate dehydrogenase (LDH), cholesterol, and glucose should be obtained,⁹ although some of the differentiating characteristics applicable to pleural effusions may not be discriminatory in pericardial effusions.¹⁰ In addition, pericardial fluid total and differential cell count, Gram stain, aerobic and anaerobic culture, and mycobacterial and fungal evaluation should be performed along with cytology when malignancy is considered. Molecular techniques can be useful in diagnosing otherwise occult infections.¹¹ Amylase is reserved for cases where pancreatic disease or esophageal rupture are part of the differential diagnosis.

Conditions predisposing to slow accumulation such as heart failure, myxedema, chronic renal failure, and connective tissue disorders in general are less likely to cause acute tamponade, whereas those associated with rapid development, such as malignancy, infection (including bacterial, fungal, and human immunodeficiency virus related), or particularly hemorrhage, commonly result in abrupt

Figure 24.4 Hemodynamic tracing of systemic pressure in cardiac tamponade, 100-mm Hg scale. Systolic pressure variation is nearly 40 mm Hg, and pulse pressure is markedly reduced during inspiration. Note the complete obliteration of the systemic pressure during deep inspiration in the beat highlighted by the arrow. Because of low stroke volume, cardiac output is being maintained to some extent by a high heart rate (146 beats per minute).

hemodynamic deterioration. The effect of inflammation in decreasing compliance of the pericardium exacerbates the hemodynamic effects of effusions associated with pericarditis.¹² The potential etiologic disorders are highly variable, with significant influence of demographics and geography, so that tamponade secondary to tuberculous pericardial effusion in immune-compromised patients is a not uncommon presentation in Africa,¹³ whereas in industrialized nations malignant effusions are a far more common cause.¹⁴ Large and usually benign pericardial effusions are seen frequently after heart transplantation, possibly immune mediated.¹⁵ Large pleural effusions can cause sufficient compression of the heart that tamponade physiology occurs.¹⁶ The most common etiologic disorders are listed in [Table 24.1](#); more detailed discussion of the various causes is presented later in the chapter, organized by the hospital setting in which presentation typically is seen.

HISTORY AND PHYSICAL EXAMINATION

Dyspnea is the most common symptom of tamponade, although its etiology sometimes is unexplained and it usually is not associated with significant concomitant pulmonary vascular congestion. It is likely to be secondary to decreased cardiac output and encroachment on lung volume by the expanding pericardium as well as any simultaneous pleural effusions. The patient may describe a sensation of fullness in the chest or abdomen and dysphagia, associated with

venous engorgement and passive congestion, stretching of the richly innervated pericardium, and occasionally vagal stimulation.¹⁷ Because most patients with tamponade have comorbid conditions accounting for their effusion, additional signs and symptoms are likely to be related to pericarditis, malignancy, or other concomitant conditions.

The hallmarks of cardiac tamponade on physical examination relate to features associated with venous hypertension, low cardiac output, and effects of the layer of fluid between the heart and the chest wall. In patients with tamponade, the general appearance changes substantially during progressive increase in pericardial pressure. Because tamponade represents a continuum, some patients with early tamponade physiology look well, whereas patients with more advanced tamponade show features of a low-output state, with clinical manifestations reflecting the high catecholamine levels required to maintain cardiac output. They become progressively more anxious and agitated and less communicative and may be struggling to breathe. Patients may complain of chest pain associated with pericardial irritation, not infrequently radiating to the neck, jaw, or shoulder¹⁸; if venous congestion is acute, patients may experience pain from stretching of Glisson's capsule around the liver.

PULSUS PARADOXUS

The physical examination in significant tamponade can include Beck's triad, described in 1935 by the surgeon C. S.

Table 24.1 Etiology of Cardiac Tamponade

Causative Disorder/Condition	Frequency (%)
Most Common*	
Idiopathic	23
Malignancy	22
Iatrogenic	18
Acute myocardial infarction	8
Purulent (including tuberculous)	8
Renal failure	3
Miscellaneous	18
Aortic dissection	
Myxedema	
Trauma	
Connective tissue disorders	
Radiation therapy	

*Frequency of common etiologies of tamponade is based on 119 cases in Barcelona, Spain. Other relatively common causes of effusion include congestive heart failure, hypoalbuminemia, coagulopathy, and postcardiotomy and Dressler's syndromes. Etiologies of tamponade will be dependent on geography and patient demographics and also will be strongly influenced by the presence of oncology, trauma, or dialysis units. For a comprehensive list of tamponade etiologies based on prior data, see Box 6.1.

Data from Sagrista-Sauleda J, Merce J, Permanyer-Miralda G, et al: *Clinical clues to the causes of large pericardial effusions*. *Am J Med* 2000;109:95-101.

Beck.¹⁹ This entity features jugular venous distention, decreased arterial pressure, and a small, quiet heart. As described earlier, pulsus paradoxus is the result of cardiac chamber interdependence and a decrease in left ventricular chamber volume with inspiration. It can be detected at the bedside by auscultation of Korotkoff sounds, identifying the highest and lowest pressures at which sounds are first heard during inspiration and expiration; alternatively, a simpler and more useful technique is to palpate the radial artery pulse with the cuff inflated to the maximum pressure at which the pulse appears and then to lower the cuff pressure in increments of 10 mm Hg to detect the pressure at which pulses are continuously noted throughout the respiratory cycle. In the patient whose systolic pressure is shown in Figure 24.4, simple palpation of the radial pulse would detect the loss of pulse pressure in the beat flagged by the red arrow. It is important to recognize that although pulsus paradoxus is a classic feature of severe tamponade, as a diagnostic feature it is of limited sensitivity and specificity.

Various thresholds other than the relatively arbitrary 10 mm Hg threshold have been proposed to increase specificity, including a 10% decrease, rather than a 10 mm Hg fall.²⁰ A drop in *systolic* pressure greater than 50% of the *pulse* pressure also has been proposed.¹ Use of a 15 or 20 mm Hg fall in pressure by physical examination is a less sensitive but far more specific finding for tamponade but may result in delayed diagnosis. Pulsus paradoxus may be present in other conditions that result in an exaggerated decrease in systolic pressure with inspiration, such as massive pulmonary embolism, severe chronic obstructive pulmonary

Box 24.1 Tamponade Settings in Which Pulsus Paradoxus May Not Be Present

- Nonrestrictive (large) atrial septal defect
- Severe aortic insufficiency
- Loculated effusion
- Left ventricular hypertrophy and other causes of elevated left ventricular diastolic pressure
- Shock due to hypovolemia, or profound circulatory collapse with tamponade
- Severe left ventricular dysfunction
- Low-pressure tamponade
- Right ventricular hypertrophy or other cause of impaired right ventricular filling
- Positive-pressure ventilation
- Arrhythmias

disease (which also can feature constrictive physiology because of limited expansion of the heart in the setting of hyperexpanded lungs),²⁰ and right ventricular infarction.²¹ Furthermore, other features of the systemic blood pressure and pulse are important to consider. With a progressive decrease in cardiac filling overall, a decline in systemic pressure (regardless of phase of the respiratory cycle) as well as a decrease in pulse pressure (the difference between systolic and diastolic pressures) occurs, reflecting decreasing stroke volume and decreasing cardiac output. Thus, it may be impossible to palpate radial artery pulsations; with severe tamponade, the patient is likely to feel cool and clammy, a finding consistent with severe peripheral vasoconstriction.

Tachycardia is almost invariable, except for comorbid conditions associated with a decrease in heart rate, such as electrical conduction disturbances, severe hypothyroidism, or aggressive β -blockade. Tachycardia is a compensatory mechanism for decreased stroke volume, is also caused by high catecholamine levels, and may result from pericardial irritation of the sinus node that stimulates a higher heart rate. On occasion, acute bradycardia may be seen in tamponade, sometimes the first finding after hemorrhage into the pericardial sac. Although a well-preserved systolic pressure and a wide pulse pressure are uncommon in tamponade, neither a low pressure nor a narrow pulse pressure is completely specific. Further, early in the course of tamponade, acute surge in catecholamine levels may result in hypertension rather than shock; in addition, patients with tamponade in the setting of renal disease and chronic hypertension appear to present more often with elevated systolic pressures.²²

The pulsus paradoxus may be absent in conditions in which ventricular interdependence is masked²³ (Box 24.1), such as a nonrestrictive atrial septal defect, in which inspiration also increases left atrial filling, or aortic insufficiency, in which left ventricular filling in diastole is increased by regurgitation from a high-pressure source: the aorta. Localized tamponade may have some general tamponade features (such as decreased stroke volume) but may not result in ventricular interdependence—hence, the clinical picture may be that of a sick patient with tamponade but without pulsus paradoxus. Markedly elevated left-sided

heart diastolic pressures in severe left ventricular hypertrophy and other disease states may exceed the elevated right atrial and intrapericardial pressures in tamponade, decreasing the effect of inspiration on the interdependence of the right and left sides of the heart. An example in which both pulse pressure and pulsus paradoxus would be insensitive markers of tamponade is aortic dissection that combines aortic insufficiency with tamponade, in which a wide pulse pressure may be seen in some patients with partial compensation, and in which pulsus paradoxus, as discussed, may be masked. By contrast, conditions resulting in impaired right ventricular filling, such as right ventricular hypertrophy in severe pulmonary hypertension, also may result in the absence of a pulsus paradoxus²⁴; furthermore, in settings such as cor pulmonale, the dramatic elevation in right-sided diastolic pressures will delay onset of the otherwise highly sensitive and early finding of right atrial and right ventricular diastolic collapse until tamponade is severe.²⁵ A substantial number of case reports describe physiologic conditions in which the classic findings for tamponade are not seen or are attributable to other etiologic disorders.²⁶

VENOUS PRESSURE

Because impairment of right-sided filling is usually the first manifestation of increasing pericardial pressure, high jugular venous pressure manifested by prominent venous pulsations may be the earliest finding on physical examination, occurring with increasing intrapericardial and right atrial pressures. Jugular venous distention may, however, be simultaneously absent because venoconstriction, a common finding with acute tamponade, makes detection of elevated venous pressures difficult. It also will be masked by low-volume tamponade, including volume-depleted states such

as trauma, when, in addition to hemorrhage into the pericardium, significant blood loss has occurred. Other settings in which venous distention may not be observed are post-dialysis in patients with uremic pericardial effusions, and excessive diuresis, sometimes as part of treatment for symptoms of congestive heart failure when the cause of elevated filling pressures has not been appreciated.²⁷ In general, lack of venous engorgement in tamponade, particularly when the latter is acute, is not uncommon. Thus, prominent jugular venous distention may suggest an alternative diagnosis, such as severe right-sided heart failure. Increased venous pressure with inspiration, Kussmaul's sign, is a feature of constriction, reflecting increased venous return to the thorax without increased right atrial filling, because the latter is constricted by the pericardium. This is in contrast with tamponade, in which negative intrathoracic pressure is transmitted through the pericardial effusion, and results in increased right-sided heart filling with decrease in venous pressure. Because these findings are difficult to differentiate in most acutely ill patients, much of the subsequent description about right atrial pressure is based on catheter based hemodynamic findings rather than the physical examination.

The Y descent, in contrast with pericardial constriction, in which it is prominent, typically is limited or absent (Fig. 24.5). Unlike in pericardial constriction, filling of the right ventricle (and hence emptying of the right atrium) is impaired throughout the cardiac cycle, because extrinsic compression by pericardial fluid results in elevated diastolic pressures in the right ventricle when rapid filling would otherwise occur. Because the pericardium allows additional atrial expansion during ventricular ejection (when ventricular volume decreases), the X descent is typically the more prominent negative pressure wave seen. The classic square

Figure 24.5 Hemodynamic tracings showing right atrial (RA) and intrapericardial pressures (incorrectly labeled LV) on a 40-mm Hg scale. Note the equivalence of pressures as well as the high mean pressure, 27 mm Hg, consistent with tamponade and hemodynamic decompensation. The Y descent is nearly absent.

root sign seen in the right ventricular pressure tracing in constriction is absent in tamponade.

In contrast with acute tamponade, with chronic effusion persistent elevation in pericardial pressure leads to a parallel rise in central and peripheral venous pressure, as well as fluid retention with elevated intravascular volume. Venous congestion as well as peripheral edema and end-organ signs of chronic venous hypertension, such as passive congestion of the liver, become more common in this setting.

CARDIAC AND CHEST EXAMINATION

The quiet heart in Beck's triad relates to several features that tend to muffle the intensity of heart sounds. First, the insulating effects of pericardial fluid on sound waves tend to decrease the sound volume transmitted to the chest wall. Second, low stroke and filling volumes tend to decrease the forces that cause the sounds generated by heart valve closure, with low pulse pressure in both the aortic and the pulmonary arteries. Because the S3 gallop is created by rapid ventricular filling, a phenomenon absent in tamponade, it would not be expected, nor would an S4, because the hemodynamic characteristics of late diastolic atrial emptying that causes the fourth heart sound are not seen.¹ A pericardial friction rub, if pericarditis is involved, may be heard. Except in severe tamponade, the pericardium around the apex of the heart may contain relatively little fluid, and left ventricular contraction typically is vigorous unless underlying left ventricular dysfunction also is present. Hence, a palpable point of maximal impulse may be felt.

A particular feature that differentiates tamponade from decompensated congestive heart failure is the typical presence of clear lungs in the case of the former. Although both right and left atrial pressures are markedly elevated, flow into the pulmonary circulation is limited, and the pressure-volume curve for the pulmonary vascular system is not affected.

DIAGNOSTIC TESTS

ECHOCARDIOGRAPHY

Echocardiography is the most easily accessible and accurate means for the timely diagnosis of tamponade and remains the diagnostic modality of choice.²⁸ Besides evaluating presence and degree of chamber collapse, the echocardiogram is useful for assessing the amount and location of effusion in the pericardial space, for characterizing the fluid, and for judging the hemodynamic effect. Cardiac tamponade represents an echocardiographic continuum, from a small accumulation of fluid with at most subtle clinical findings, to large, usually circumferential²⁹ accumulations with resultant cardiogenic shock. Until effusions are at least moderate in size, fluid may be shifted by gravity to a location primarily posterior to the heart, because most patients are recumbent during echocardiography (Fig. 24.6).

Several echocardiographic features have been described in tamponade that result from an increase in intrapericardial pressure. These include exaggerated late diastolic right atrial collapse, early diastolic right ventricular collapse, significant respiratory variation in Doppler inflow velocities

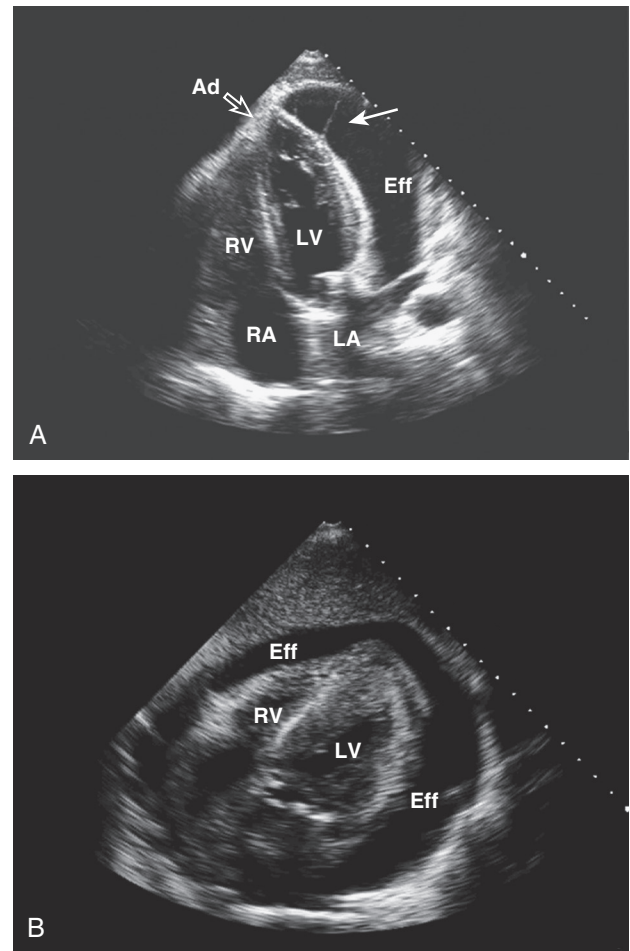

Figure 24.6 Echocardiographic images of two types of pericardial effusions. **A**, A large posterior pericardial effusion, with relatively little fluid anterior to the heart or at the apex. The apex is adherent to the pericardial surface. The arrow points to a fibrous strand. This is a fairly typical appearance of a chronic postcardiotomy effusion. Needle access would be problematic. **B**, By contrast, this effusion is circumferential, with somewhat more fluid behind the left ventricle, a largely gravitational effect. Leaning the patient forward 20 to 30 degrees would facilitate pericardiocentesis, although the patient was not significantly hemodynamically compromised. Ad, adhesion; Eff, effusion; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

across the tricuspid and mitral valves, a plethora of the inferior vena cava, exaggerated expiratory flow reversal of the hepatic veins, and blunted diastolic flow of the inferior vena cava (IVC) during expiration.³⁰ Because the right-sided cardiac chambers are more compliant, thin walled, and at relatively low pressure, the increase in intrapericardial pressure results in the collapse of these chambers first.

Immediately after atrial contraction, the right atrial volume is at its lowest, whereas right ventricular volume is at its maximum; total pericardial volume in cardiac tamponade is relatively fixed. The increase in ventricular filling during diastole increases pericardial pressure, which prevents expansion of the right atrium during atrial relaxation (late ventricular diastole).³¹ Persistence of right atrial collapse for more than one third of the cardiac cycle is a useful marker for early tamponade physiology. This phenomenon

is best appreciated from the apical or subcostal four-chamber views (see Fig. 8.43 in Chapter 8).

The right ventricle, conversely, is more vulnerable to collapse during early diastole, when its pressure is at its lowest as it expands following closure of the pulmonic valve. The right ventricular outflow tract is the more compressible area of the right ventricle and hence tends to collapse first.³⁰ With increasing intrapericardial pressure, the collapse extends to the right ventricular free wall, which is best appreciated on parasternal long or short axis views (see Figure 8.44 in Chapter 8). This is a more specific finding for tamponade than right atrial collapse, as the latter can occur in the setting of hypovolemia alone. However, right ventricular diastolic collapse may not be seen in conditions that result in significantly elevated right ventricular diastolic pressure or in right ventricular hypertrophy. Collapse of the higher-pressure left-sided chambers, particularly the left ventricle, is uncommon, but, when seen, is highly specific for tamponade. Collapse of the left atrium is not uncommon in the immediate postcardiac surgery period, frequently a result of loculated effusion causing regional tamponade.³²

Although cardiac chamber collapse is a highly sensitive marker and typically seen before clinical manifestations of tamponade, a number of other findings are more specific. As discussed previously, pulsus paradoxus results from exaggerated ventricular coupling. The ventricular interdependence (Fig. 24.7) can be appreciated on echocardiography by demonstration of marked respiratory variation of Doppler flow across the atrioventricular or semilunar valves (see also Figs. 8.43 and 8.44 in Chapter 8). During inspiration, the drop in intrathoracic pressure results in increased right ventricular (RV) filling. As right ventricular cavity size increases during diastole, the increased intrapericardial pressure impairs expansion of the right ventricular free wall, and continued RV filling is accomplished only by diastolic expansion of the interventricular septum. The consequent bulging of the interventricular septum into the left ventricular (LV) cavity during diastole results in marked reduction in LV compliance and inspiratory filling.^{12,33} These filling changes are reflected in a marked inspiratory increase in tricuspid valve Doppler inflow velocities with simultaneous inspiratory decrease in mitral valve inflow velocities.

Figure 24.7 Classic findings for ventricular interdependence in cardiac tamponade. See the legend for Figure 8.45 in Chapter 8.

Reciprocal changes are noted during expiration. A corollary to these respiratory changes is noted in the hepatic vein and vena cava flow patterns. Normal vena cava flow into right atrium occurs during both ventricular systole and diastole. In tamponade, already impaired diastolic flow is further compromised in expiration by the exaggerated ventricular interdependence. This hemodynamic effect manifests on Doppler as blunted diastolic caval flow during expiration with increased expiratory flow reversal in the Doppler flow pattern of hepatic veins³⁴ (Fig. 24.8). Although it is expected that in tamponade the IVC will be dilated and nonreactive,³⁵ a plethora of the IVC can be seen in any condition causing elevation of right atrial pressure, including positive pressure ventilation in an intubated patient.

Portable echocardiography, performed at the bedside, in the emergency room, or in critical care units, is highly reliable in cardiac tamponade.^{36,37} However, adequate training in basic technique and fundamental anatomy is essential to avoid misdiagnosis. Epicardial fat can be confused with effusion,³⁸ and isolated or coexistent pleural effusions, mediastinal masses, and atelectasis can confound the diagnosis as well.³⁹ It is important to assess the heart from as many echo windows as possible for small but opportunistic loculated accumulations of fluid, for the presence of clot, fibrinous “strandlike” material or masses, and for compression from processes outside the pericardium, such as a mediastinal hematoma and pleural effusion, all of which will significantly impact management.

X-RAY STUDIES

The classic “water bottle” configuration of the heart is due to a large pericardial effusion and therefore occurs only if the pressure-volume curve has altered sufficiently through chronic accumulation to allow significant increase in pericardial volume. It is a misconception that a normal-sized heart excludes tamponade; in acute tamponade the heart size can be expected to appear normal or minimally enlarged.¹² With marked enlargement of the cardiac silhouette, the finding is nonspecific and not readily distinguishable from cardiomegaly, although in tamponade pulmonary vascular congestion is usually not seen, whereas prominence of the vena cava may be noted. Other modalities such as computed tomography (CT) scanning and magnetic resonance imaging (MRI) show large effusions and can demonstrate chamber collapse. In addition, characterization of pericardial thickness and of the pericardial fluid to differentiate between blood and fluid of different densities can be useful. Although CT and MRI show primarily anatomy rather than physiology, they can identify chamber collapse, characterize soft tissue, and demonstrate reflux into the azygous vein, a useful sign of tamponade.⁴⁰ CT scanning can provide information supplemental to that seen on echocardiography, including identification of extracardiac disease lesions,⁴¹ and can provide additional sensitivity for the detection of loculated effusions.⁴² Coronary sinus compression on CT is an early and specific indicator of tamponade.⁴³

ELECTROCARDIOGRAPHY

The classic electrocardiographic features include low voltage, a result of poor transmission of electrical activity

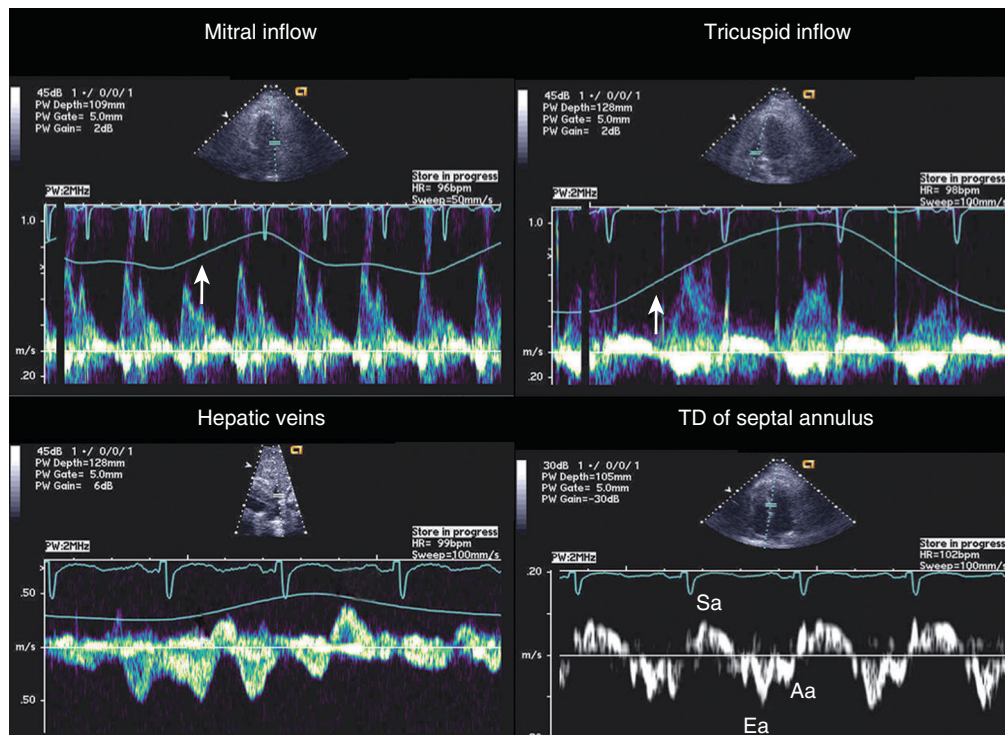

Figure 24.8 Pulsed Doppler signal of hepatic vein showing reduced forward flow (arrows) and increased diastolic flow reversal during expiration (E) in tamponade. I, inspiration.

Figure 24.9 Electrocardiogram demonstrating classic electrical alternans in a patient with pericardial tamponade. Note the change in amplitude of the R wave in lead V1 (red oval). Similar findings are seen throughout the limb and precordial leads shown.

across the fluid in the pericardial space, and electrical alternans, an insensitive but relatively specific finding for tamponade generated by swinging of the heart in the fluid-filled chamber (Fig. 24.9). Electrical alternans typically is seen only with large effusions in the later stages of tamponade, although the finding is related more to fluid volume and the ability of the heart to swing within the pericardial space. It may involve alternans of both QRS complexes and P waves. Thus, tamponade with adhesions (Fig. 24.10), loculation, or masses that restrict heart motion may not manifest the alternans phenomenon.

OVERALL ASSESSMENT

In general, the severity of tamponade can be judged by the extent of hypotension, tachycardia, and pulsus paradoxus on physical examination and confirmed by findings on echocardiography.⁴⁴ Mild tamponade features no hypotension or tachycardia, and no pulsus, with mild RV collapse by echo. Patients with moderate tamponade have preservation of systemic pressure, but have tachycardia, some degree of pulsus paradoxus, and clear RV collapse on echo. Severe

Figure 24.10 Echocardiogram showing pericardial tamponade with right-sided collapse, adhesion of the right ventricle to the pericardium (arrow), and fibrous strands of early adhesions seen at the 1 o'clock position near the apex of the left ventricle. Even if the effusion accumulates further, electrical alternans would be less likely because of lack of mobility of the heart. Ad, adhesion; Eff, effusion; LV, left ventricle; RV, right ventricle.

tamponade is associated with tachycardia, shock, profound pulsus paradoxus, and chamber collapse with a swinging heart on ultrasound.²¹ Hemodynamic findings correlate with increasing pericardial pressure at each stage of tamponade,⁴⁵ initially less than right atrial or pulmonary wedge pressure, then equilibrating with right but less than left atrial pressure, and in severe tamponade equilibrating with both.

SPECIAL SYNDROMES IN TAMPONADE

Although most cases of tamponade have at least some of the classic features, there are several important variants. Loculated effusions that compress the heart primarily in one region are typically postsurgical, although they may be due to neoplasms or a number of other etiologies; they are discussed in the section on postcardiac surgery cases that follows. There are also a number of conditions where pulsus paradoxus does not occur or is masked, summarized in [Box 24.1](#).

EFFUSIVE CONSTRICTIVE DISEASE

This phenomenon is an important-to-recognize condition occurring in less than 10% of patients with tamponade,⁴⁶ but up to 40% in some series. Hospitals with disproportionately high populations of oncology patients, because of tumor metastases or postradiation pericardial involvement, or tuberculosis, will have a higher percentage of tamponade patients with this diagnosis. The syndrome can occur after acute pericarditis of multiple etiologies and may even be transient.⁴⁷ The classic features of tamponade are seen on presentation, and a history of malignancy should increase the suspicion of prepericardiocentesis.

Effusive constrictive disease is a setting in which careful hemodynamic monitoring is very helpful for accurate diagnosis. Monitoring of intrapericardial and right atrial or wedge pressure during pericardiocentesis demonstrates findings as seen in [Figure 24.11](#). In general, with relief of tamponade intrapericardial hypertension resolves, and classic respiratory variation is seen in most patients, whereas right atrial pressure remains elevated though lower than prior to the pericardiocentesis. The Y descent becomes prominent because of the elimination of high transmural pressures that restrict filling during early diastole in tamponade, unmasking classic constrictive physiology. [Figure 24.12](#) shows echocardiographic images in a typical patient with this syndrome.

LOW- AND HIGH-PRESSURE TAMPONADE

Low-pressure tamponade has been defined as featuring hypotension secondary to pericardial effusion but with low venous and intrapericardial pressures, most commonly in the setting of hypovolemia resulting from dehydration or blood loss. A more formal definition, based on a single site experience, was described by Sagrista-Sauleda and colleagues⁴⁸ as an intrapericardial pressure less than 7 mm Hg, with a post-pericardiocentesis right atrial pressure less than 4 mm Hg and equalization of intrapericardial and right atrial pressures before pericardiocentesis. Importantly, 20% of their patients with cardiac tamponade met these criteria (and 10% of their patients with large pericardial effusions), suggesting that low-pressure tamponade, previously the subject primarily of case reports and small series, may be more common than previously appreciated. Because of low pressures, there is a lack of features such as pulsus paradoxus or jugular venous distention, with only 24% demonstrating these classic findings, making the diagnosis significantly more difficult. Fluid challenge may result in more typical findings.

Patients with chronic hypertension in whom tamponade develops occasionally have high blood pressure despite tamponade physiology, presumably because of an exaggerated systemic pressure response to the catecholamine storm associated with tamponade.⁴⁹ In this setting, injudicious use of the usual medications to lower blood pressure can result in profound hemodynamic compromise.

SETTINGS IN WHICH TAMPONADE IS SEEN

THE EMERGENCY ROOM

The primary cause of tamponade in the emergency room relates to hemopericardium, although the complete range of medical etiologies can be seen in this setting. Trauma⁵⁰ includes gunshot and stab wounds, as well as penetrating and crush wounds to the chest, including those related to automobile accidents. Penetrating wounds are significantly more likely to result in tamponade than crush injuries.⁵¹ Medical presentations with acute hemopericardium include aortic dissection with tamponade, postmyocardial infarction rupture, or leaking thoracic aneurysm, situations in which pericardiocentesis may lead to further hemodynamic

Figure 24.11 Hemodynamic tracings (40-mm Hg scale) obtained 1 hour after those seen in Figure 24.5. After pericardiocentesis of 1 L of fluid, the pericardial pressure has achieved a mean equivalent to atmospheric pressure (0 mm Hg by convention), while right atrial pressure remains elevated near 22 mm Hg. This is physiology consistent with effusive-constrictive disease. On removal of the effusion, the hemodynamics, including the newly seen steep Y descent, are classic for constriction. This patient had a malignant pericardial effusion. P, intrapericardial pressure; RA, right atrium.

decompensation,^{52,53} as well as hemopericardium secondary to overanticoagulation. In general, acute hemopericardium may be associated with continued hemorrhage as well as clot in the pericardium; the latter makes complete drainage difficult. Clot alone can compress the heart and cause tamponade-like physiology. The clinical presentation of acute intrapericardial hemorrhage is typically shock, and jugular venous distention may or may not be present because of venoconstriction and hypovolemia as previously described. Use of echocardiography in the emergency room in patients with unexplained dyspnea is an important diagnostic tool.⁵⁴

THE CARDIAC CATHETERIZATION AND ELECTROPHYSIOLOGY LABORATORIES

Perforation of the heart, including coronary arteries and cardiac chambers, during invasive cardiac procedures has become an increasingly important cause of pericardial tamponade.⁵⁵ Common scenarios include electrophysiology procedures, where relatively stiff catheters are placed in the relatively thin-walled structures of the right heart, including

the right atrium, right ventricle, and the coronary venous system including the coronary sinus. Anticoagulation, when required for electrophysiology procedures, such as those involving left atrial ablation, raises the risk substantially. Perforation of coronary arteries occurs in particular with atheroablation devices such as those used for rotational atherectomy, directional atherectomy and lasers, with guidewires used in chronic total occlusions or injudiciously manipulated distal to the target lesion, and with oversized balloons and stents.⁵⁶ Even with normal sizing, settings such as myocardial bridges or ruptured balloons are associated with vessel perforation or rupture. A third setting is transseptal puncture, a resurgent technique because of burgeoning technologies requiring left atrial access⁵⁷ but associated with a significant risk of tamponade.⁵⁸ Besides left-sided ablations, mitral valvuloplasties, and percutaneous circulatory bypass (with its intake source in the left atrium), transseptal puncture is required for a number of techniques under development, including left atrial appendage occlusion and percutaneous mitral valve repair. The risk of pericardial effusion and tamponade with these interventions

Figure 24.12 Echocardiographic images from a patient with effusive-constrictive disease. **A**, Tamponade. *Curved arrow* points to needle in pericardial space; *straight arrow* points to tumor mass. The pericardium is thickened. **B**, Agitated saline has been injected through the needle (*arrow*) to confirm entry into the pericardial space. Eff, effusion; LV, left ventricle.

contributes significantly to their overall morbidity and mortality.⁵⁵ However, and somewhat counterintuitively, electrophysiologists now frequently anticoagulate prior to transeptal puncture or perform the procedure in patients already on full oral anticoagulation.⁵⁹ This practice is driven by fear of thromboembolism rather than tamponade, the former an important complication of left-sided ablations in particular, which can be long procedures, and associated with clot inducing char formation. Other endovascular procedures associated with tamponade include myocardial biopsy and central venous line placement, pacemaker lead extraction, as well as erosion of devices implanted across the atrial septum or in the left atrial appendage.⁶⁰

The potentially catastrophic setting of free perforation during coronary interventions is usually readily diagnosable during the procedure, with free flow in the pericardium seen during coronary injection, sometimes before the patient shows any signs of hemodynamic deterioration. This is readily treatable with balloon occlusion of the coronary artery at the perforation site, pericardiocentesis if necessary, and excluding the fenestration with a covered stent. However, lower-grade perforations that result in pooling of contrast or small adventitial craters can be more subtle. It

Figure 24.13 Echocardiogram showing large circumferential pericardial effusion in myxedema. Severe tamponade is rare. Eff, effusion; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

is essential to discontinue anticoagulation on such patients and consider heparin reversal, and to ensure that personnel responsible for postprocedure management monitor the patient closely for hypotension and tachycardia. With transeptal punctures, hypotension at any time during the case, but especially after anticoagulation is administered, should raise the possibility of tamponade. A quick and relatively specific finding in the catheterization laboratory is straightening and lack of motion of the left heart border on anteroposterior fluoroscopy associated with hypotension (and sometimes reflex bradycardia); rapid intervention is essential in these patients. Hypotension after the procedure should raise the possibility that left atrial access involved a “stitch perforation” whereby the needle exited the right atrium and then entered the left atrium through the pericardial space; this mishap is possible with low punctures and frequently manifests only when catheters are removed from the fenestration at the end of the procedure. In patients who have had pacemaker placement, tamponade can develop acutely or after considerable delay as in the case of lead erosion.⁶¹

CRITICAL CARE UNITS AND MEDICAL WARDS

Tamponade in the critical care unit typically is due to complications of myocardial infarction, concomitant sepsis with purulent pericarditis, or hemorrhage into the pericardium because of anticoagulation (either iatrogenic or endogenous) or, most commonly, is secondary to neoplasms. In myocardial infarction, tamponade can be acute, secondary to massive or limited rupture, or somewhat more insidious in onset as part of Dressler’s syndrome, with hemodynamic compromise sometimes exacerbated by anticoagulation. Tamponade also can be iatrogenic, in particular, secondary to placement of various lines through the venous or arterial circulation. Uncommon causes of tamponade, even with pericardial effusions of sometimes significant size, are viral pericarditis, congestive heart failure, uremia, myxedema (Fig. 24.13), and connective tissue disorders.

In patients with malignancy, several possible causes of tamponade are seen, including tumor involvement in the pericardium, postradiation pericarditis, graft-versus-host disease, and direct or indirect complications of therapy.⁶² Patients with malignancies also are at increased risk for infectious pericarditis, coagulopathies or thrombocytopenia with secondary hemorrhage, and hypothyroid- and hypoalbuminemia-related effusions. AIDS and other immunosuppressed patients similarly are predisposed to infectious tamponade, as well as pericardial tumor involvement, including that from lymphoma. The mechanisms of pericardial effusion in cancer are varied but include direct spread to the pericardium from primary tumors such as lung, mediastinal, and esophageal cancer; hematogenous spread such as with lymphomas; and obstruction of the lymphatic drainage of the heart by tumors in the mediastinum.

Tamponade after cardiac surgery is an important phenomenon, usually occurring as a result of hemorrhagic effusion. Early postoperative tamponade is not uncommon and is important to recognize as a cause of hypotension because it has been reported to occur with a frequency of 5% to 10%, although this generally is thought to be in the 1% range in the modern era.⁶³ Moderate to large pericardial effusions that do not cause hemodynamic compromise have been much more common.⁶⁴ Delayed tamponade after heart surgery, with onset on average at 2 to 3 weeks postoperatively but as late as 6 months or more, occurs in less than 1% of patients but is disproportionately more common in patients undergoing valve surgery, probably related to postoperative anticoagulation in this cohort.^{65,66} Delayed tamponade probably is a variant of the more common postcardiotomy syndrome.

Late tamponade typically is due to loculated effusion resulting from formation of adhesions (see Figs. 24.6 and 24.10) during recovery from surgery. Such adhesions can cause decreased cardiac output if they compress the left side of the heart, and in some cases pulmonary edema occurs if obstruction to inflow results. A variety of clinical problems related to increased right-sided heart pressure occur when tamponade involves the right side, including a clinical picture that resembles superior vena cava syndrome; several case reports have described right-to-left shunting across a patent foramen ovale as well.⁶⁷ Pericardiectomy to prevent postoperative tamponade has an uncertain risk-benefit ratio but does appear to decrease the incidence of hemodynamic compromise.⁶⁸

Patients on dialysis present a special diagnostic and management problem. With underdialysis, volume overload can exacerbate chronic fluid accumulation in the pericardial space. Hypotension during or after dialysis may be secondary to inadequate intravascular volume and diminished venous pressure and needs to be avoided as well.

MANAGEMENT

Pericardial tamponade is life threatening, requiring difficult diagnostic and, in particular, management decisions. When hemodynamics do not suggest significant compromise and effusion is small to moderate in volume, intervention frequently is not necessary and may involve increased risk to the patient, whereas late intervention may be fatal. Typically,

the risk associated with pericardiocentesis is inversely related to the volume of accumulated fluid and also is related to the location of the effusion. Thus, relatively small effusions, early in the course of tamponade, usually are located primarily posteriorly because of gravity-dependent accumulation. Waiting until the effusion is large and occupies significant volume anteriorly decreases the risk of percutaneous drainage but increases the possibility of decompensation and death before intervention. Frequent monitoring of hemodynamics and the application of sound clinical judgment are essential, but an optimal algorithm does not exist. Comorbid conditions such as endogenous or extrinsic anticoagulation may substantially confound the situation.⁶⁹ The clinical decision to drain the effusion percutaneously or to send the patient for thoracotomy will be a function of the clinician's assessment of risk of the former versus the potential advantages of surgery in obtaining pericardial tissue and providing a pericardial window as well. If the percutaneous approach is chosen, performing pericardiocentesis in the cardiac catheterization laboratory has significant advantages. However, the benefit of positioning the pericardial effusion anteriorly, for increased safety during needle entry into the pericardial space, requires that the patient's chest be elevated during the procedure, which typically can be accomplished only to a 20- or 30-degree angle on most catheterization tables because of the image intensifier unless the table has tilt capabilities. A moribund patient frequently needs pericardiocentesis performed at the bedside without fluoroscopic guidance, sometimes without adequate hemodynamic monitoring, and at times without echocardiographic monitoring—all of which are associated with increased risk of failed pericardiocentesis and adverse cardiac events. Patients with severe tamponade are often anxious and hypoxic; sedation is hazardous as is intubation, though the latter is at times necessary. As a result of associated positive intrathoracic pressure, intubation may cause abrupt hemodynamic deterioration because it decreases venous return to the heart.² Cardiopulmonary resuscitation using chest compression is unlikely to be effective; immediate pericardiocentesis or thoracotomy are ordinarily the only possibilities for survival. Further discussion of percutaneous interventions for tamponade can be found in Chapter 6.

Little in the way of medical treatment is clearly therapeutic for tamponade. Volume expansion in relatively acute tamponade will support right-sided filling in patients with low circulatory volumes, such as are seen in trauma.⁷⁰ Patients with chronic tamponade typically have considerable fluid retention, and additional hydration is unlikely to be of benefit. Pressors may be modestly helpful, but for patients with preserved cardiac function, catecholaminergic drugs provide only modest augmentation of cardiac output; patients with hemodynamically important tamponade are usually already maximally catecholamine stimulated. Vasodilator therapy is less clearly beneficial, and drugs that decrease preload, such as nitrates and nitroprusside, should be avoided if the patient is hypotensive. Reversal of anticoagulation is essential, both to stop bleeding into the pericardial space and to decrease the risk of trauma to the heart or major blood vessels during pericardiocentesis (e.g., coronary arteries, hepatic vessels). The introduction of direct thrombin inhibitors may affect this portion of the

management algorithm because they are not reversible with vitamin K, and there are anecdotal reports of tamponade occurring after the introduction of oral versions of these agents⁷¹ as well as failed pericardiocentesis during percutaneous coronary intervention associated with bivalirudin administration.⁷² Antibiotic therapy in the setting of purulent pericarditis and tamponade is not expected to acutely relieve hemodynamic decompensation in most settings; postdrainage treatment, including local infusion of drugs, is discussed in Chapter 6. A targeted approach for patients with malignant pericardial disease includes the use of sclerosing agents combined with antineoplastic drugs infused into the pericardial space, sometimes combined with radiation; a variety of such management strategies continue to be applicable for some cancer patients.⁷³ Leaving an indwelling drain is controversial because of the associated risk of infection, although there is some evidence that it can decrease the risk of recurrent tamponade.⁷⁴ An excellent review of the clinical approach to pericardial disease in general has been published by the European Society of Cardiology.⁷⁵

ACKNOWLEDGMENT

The author wishes to acknowledge Priscilla Peters for kindly providing Figures 24.6, 24.7, 24.8, 24.10, 24.12, and 24.13.

KEY POINTS

- Pericardial tamponade represents a continuum, ranging from effusions associated with little or no hemodynamic compromise to hemodynamic collapse.
- The primary physiologic feature of tamponade is impairment of cardiac chamber filling due to high intrapericardial pressure, with a resultant decrease in cardiac output.
- Acute tamponade occurs after a relatively limited accumulation of fluid in the setting of a nondistensible pericardium.
- Chronic tamponade may involve a pericardial effusion of 1 L or more; because hemodynamic decompensation occurs in the steep part of the pressure-volume curve, accumulation of a small amount of additional fluid can result in substantial hemodynamic deterioration.
- Pulsus paradoxus is seen in a variety of conditions besides cardiac tamponade and is absent despite

KEY POINTS (Continued)

- tamponade in a number of settings. A large pericardial effusion and right ventricular collapse, a 10 to 20 mm Hg or larger decrease in systolic pressure with inspiration, and a significant decline in pulse pressure combined are specific for tamponade.
- Right atrial pressure, except in settings such as hypovolemia, usually is significantly elevated, but jugular venous distention may not be seen with acute tamponade.
- Despite markedly elevated right and left atrial pressures, pulmonary vascular congestion usually is not seen.
- Persistent high right atrial pressure after fluid drainage suggests effusive-constrictive disease, most commonly associated with malignancy but also seen with infection and acute pericarditis.
- Management of pericardial tamponade involves determining the optimal timing and method of intervention. Fluid and drug therapy constitute modest adjunctive care only.

Organ Dysfunction Scoring Systems

INTRODUCTION

The term *sepsis* is derived from the Greek word *sepsin*, which means “to make putrid.” The relationship between infection and sepsis has been recognized for many years. However, the precise mechanisms by which infection results in sepsis, severe sepsis, septic shock, or multiple organ dysfunction remain to be fully elucidated. Improvements in our understanding of this syndrome have led to the development of novel therapeutic strategies and have increased our appreciation for the complex interactions that exist in sepsis between pathogens and the host response to infection. Despite these advances, severe sepsis remains one of the most significant causes of morbidity and mortality in patients admitted to the intensive care unit (ICU).¹ In this chapter we will discuss the current definitions, epidemiology, and pathogenesis of severe sepsis and multiple organ dysfunction. In addition, we will review current management options and discuss an approach to treatment based on pathophysiology.

DEFINITIONS

For many years the term *sepsis* was loosely applied in clinical practice and was used to describe a very heterogeneous patient population. In recognition of this problem, a consensus conference was convened to create standardized definitions and formulate a blueprint to guide future research in sepsis.² The term *systemic inflammatory response syndrome* (SIRS) was introduced. SIRS can occur in response to a

variety of severe clinical insults and is defined by the presence of two or more of the following conditions: (1) temperature $> 38^{\circ}\text{C}$ or $< 36^{\circ}\text{C}$, (2) heart rate > 90 beats per minute, (3) respiratory rate $>$ breaths per minute or a $\text{PaCO}_2 < 32$ mm Hg, and (4) white blood cell count $> 12,000$ cells/mm³. *Sepsis* occurs when SIRS is caused by infection. *Severe sepsis* is sepsis with associated organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. *Septic shock* is defined by the presence of sepsis-induced hypotension (systolic blood pressure < 90 mm Hg or a reduction ≥ 40 mm Hg from baseline in the absence of other causes for hypotension), despite adequate fluid resuscitation along with the presence of perfusion abnormalities.² The introduction of these definitions created a common language that was especially helpful in designing and defining populations for clinical trials.³ On the other hand, criticism of these definitions pointed out that they were too sensitive and were not useful when applied clinically to individual patients.⁴ In 2001 a second consensus conference with a broader representation was convened to revisit these definitions.⁵ The conference recommended keeping the 1992 definitions unchanged secondary to lack of new evidence to support new definitions. However, the consensus conference recommended expanding the diagnostic criteria for sepsis in an effort to enhance recognition at the bedside (Box 25.1). In addition, the Predisposition Insult infection Response Organ dysfunction (PIRO) system for staging sepsis was proposed. This staging system is still relatively new and further development and research will be needed prior to its implementation in clinical practice. Examples and

Table 25.1 The PIRO System for Staging Sepsis

Domain	Present	Future
Predisposition	Premorbid conditions, age, and sex	Genetic polymorphism in components of the inflammatory response (e.g., TNF)
Insult infection	Culture and sensitivity of pathogens; identification of possible target for source control	Assays of specific microbial products and gene transcript profiles
Response	SIRS, other signs of sepsis, septic shock, C-reactive protein	Markers of activated inflammation or impaired host responsiveness
Organ dysfunction	Organ dysfunction as number of failing organs or composite scores	Measure of cellular response to insult-apoptosis, cytopathic hypoxia, cell stress

SIRS, systemic inflammatory response syndrome; TNF, tumor necrosis factor.

Adapted from Levy M, Fink MP, Marshall JC, et al: 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. *Crit Care Med* 2003;31:1250-1256.

Box 25.1 Diagnostic Criteria for Sepsis

Infection, documented or suspected, plus some of the following findings:

Temperature > 38.3°C or > 36°C
 Heart rate > 90 min or > 2 SD above normal value for age
 Arterial hypotension (SBP < 90 mm Hg, MAP < 70 or an SBP decrease > 40 in adults or < SD below normal for age)
 Mixed venous oxygen saturation (SvO₂) > 70%
 Cardiac index > 3.5 L/min/M²
 Tachypnea
 Decreased capillary refill or mottling
 Altered mental status
 Significant edema or positive fluid balances
 Hyperglycemia in the absence of diabetes
 WBC count > 12,000 μL or < 4000 μ
 Normal WBC with > 10% immature forms
 Plasma C-reactive protein > 2 SD above the normal value
 Plasma procalcitonin > SD above the normal value
 Hyperlactatemia (> 1 mmol/L)
 Evidence of organ dysfunction:
 Arterial hypoxemia (PaO₂/FiO₂ < 300)
 Acute oliguria
 Creatinine increase > 0.5 mg/dL
 Coagulation abnormalities (INR > 1.5 or a PTT > 60s)
 Ileus
 Thrombocytopenia
 Hyperbilirubinemia

possible measures for the future in each domain are shown in Table 25.1.

EPIDEMIOLOGY

Severe sepsis constitutes a major health care problem.⁶⁻⁸ Estimates of the incidence of severe sepsis in the United States report that approximately 750,000 cases occur

per year (3 cases per 1000 population).⁶ Almost 70% of these cases receive care in a high dependency unit (ICU, intermediate care unit, or coronary care unit).⁶ The incidence of severe sepsis and septic shock has increased over time both in North America and in Europe.⁶⁻⁸ The incidence of severe sepsis is projected to increase by 1.5% every year.⁶ These increases in incidence are attributed to an aging population with a growing number of patients with a compromised immune system, infected with resistant pathogens, and undergoing prolonged, high-risk surgical interventions.⁸ Severe sepsis is more frequent with increased age, in males, and in nonwhite patients.^{6,8} Before the mid-1980s, gram-negative bacteria were the most common pathogens responsible for severe sepsis. Over the years an increase in cases from gram-positive bacteria has been reported, and today gram-positive bacteria are the predominant pathogens in severe sepsis.⁸ The incidence of sepsis resulting from fungal organisms has increased substantially since the 1990s.⁸ The most common sites of infection include the respiratory system, the bloodstream, and the genitourinary tract.^{6,7,9}

Although mortality for severe sepsis and septic shock has decreased over time, severe sepsis still kills one in four patients affected worldwide.^{6,7,10,11} Mortality increases with age in black men and with increased number of failing organs.⁸ Over time the hospital length of stay for patients with sepsis has decreased, and the number of discharges to nonacute medical care facilities has increased.⁸ In addition to causing high morbidity and mortality, severe sepsis has a significant economic impact. Estimates report an average cost per patient of \$22,000, representing an annual impact to the health care system in excess of \$16.5 billion in the United States alone.⁶

PATHOPHYSIOLOGY

Severe sepsis is the result of complex interactions between infecting organisms and the host response. Important components of this host response in the early phases of sepsis include the immune system, activation of the inflammatory cascade, and alterations in hemostasis. In later stages of sepsis, organ failure, immunosuppression, and apoptosis

play an important pathophysiologic role. Both characteristics of the infecting organism and of the host response influence the outcome of sepsis. Virulence factors, high burden of infection, and resistance to antibiotics are all organism characteristics associated with increased risk of severe sepsis. There is a growing body of literature suggesting that host responses might be influenced by genetic polymorphisms.¹²⁻¹⁷ This might explain why some patients develop severe sepsis to a particular pathogen and others do not. We will further discuss some of the relevant components of the host response in severe sepsis.

ROLE OF THE IMMUNE SYSTEM IN THE EARLY PHASES OF SEPSIS

The immune response to infection takes place through the actions of two pathways: the innate immune system and the adaptive immune system. The goal of the innate immune system is to provide protection in the first minutes to hours after an infectious challenge. Although initially thought to be a nonspecific response, research has demonstrated that the innate immune system recognizes pathogens by means of pattern-recognition receptors (Toll-like receptors [TLRs], [Table 25.2](#)). Toll-like receptors bind to highly conserved structures on microorganisms, which are not easily altered by microbes to evade detection and are present on broad groups of organisms.¹⁸ Our current understanding of TLRs suggests that the immune cells use different TLRs to detect several features of an organism and based on the composite information gained generate a tailored response to the invading pathogen.¹⁸ Activation of Toll-like receptors by microorganisms stimulates signaling pathways that increase production of pro-inflammatory cytokines such as tumor necrosis factor (TNF- α), interleukin-1 β (IL-1 β), and nuclear factor- κ B (NF- κ B), as well as anti-inflammatory cytokines such as interleukin-10 (IL-10).^{18,19} Toll-like receptor

activation also results in up-regulation of microbial killing mechanisms, such as the production of reactive nitrogen species.²⁰ Toll-like receptors play a pivotal role in initiating the innate immune response and are important regulators of the adaptive immune response to infection. Recognition of these proteins and their functions expanded our understanding of the pathophysiology of sepsis and has provided a new target for therapeutic interventions.²¹

The adaptive immune system amplifies the response initiated by the innate immune system with a higher degree of specificity. In addition to their interactions with the innate immune system, microorganisms stimulate specific cell-mediated and humoral adaptive immune responses. Two types of lymphocytes, B cells and T cells, play an important role in the adaptive immune response. Adaptive immune responses (humoral and cellular) require days to develop. However, they are amnestic through the generation of memory T and B lymphocytes and, in the case of reexposure to the same pathogen, can elicit a faster response. CD4 T cells are divided into two types: type 1 helper T-cell (Th1) and type 2 helper T-cell (Th2). Factors such as type of organism, site of infection, and burden of infection influence the response elicited by T cells. In general, Th1 cells secrete pro-inflammatory cytokines (TNF- α and interleukin-1 β) and Th2 cells secrete anti-inflammatory cytokines (interleukin-4 and interleukin-10).²² B lymphocyte cells are responsible for releasing immunoglobulins in response to microorganisms. These immunoglobulins bind to organism-specific antigens and enhance recognition and destruction by other immune cells (natural killer cells and neutrophils). Several other cell types are involved in the adaptive immune response to infection ([Fig. 25.1](#)).

ROLE OF INFLAMMATION

For many years the prevailing theory has been that sepsis is the result of an uncontrolled inflammatory response.^{1,2} This paradigm was based on extensive animal experimentation with models of inflammation that may not necessarily reflect human disease. Animal models of sepsis that utilized large doses of endotoxin or bacteria created a “cytokine storm” that when blocked resulted in improvements in mortality. However, in human sepsis most patients have a complex host response that includes activation of both pro-inflammatory and anti-inflammatory cascades. Early death from overwhelming inflammation is not the norm, and most patients who die develop complications related to immunosuppression, apoptosis, and multiorgan failure later in the course of the disease. These differences may partially explain why so many anti-inflammatory compounds worked in animal models yet failed to improve mortality in human clinical trials. The interplay between pro-inflammatory cytokines, anti-inflammatory cytokines, and cytokine inhibitors is a dynamic process that influences the host response to sepsis. Pro-inflammatory cytokines such as TNF- α and IL-1 β increase early in sepsis and have overlapping and synergistic effects in further stimulating the inflammatory cascade.²³ Pro-inflammatory cytokines activate monocytes, macrophages, and neutrophils; stimulate neutrophil margination; and increase gluconeogenesis. In addition, pro-inflammatory cytokines have an important role in the development of clinical abnormalities such as

Table 25.2 Role of TLRs in Pathogen Recognition and Pathophysiology of Human Disease

Toll-like Receptor	Pathogen or Disease State

TLR10	Unknown

Figure 25.1 Response of immune cells to infection. The immune response to pathogens involves various types of cells. Crosstalk exists between the different cell lines of the immune system (dendritic cells, macrophages, lymphocytes, and neutrophils). The + sign represents up-regulation, and the – sign down-regulation. Many interactions on the figure have both + and – signs, representing the possibility of either up-regulation or down-regulation, depending on a variety of factors. (Adapted from Hotchkiss RS: The pathophysiology and treatment of sepsis. *N Engl J Med* 2003;348:138-150, Figure 1, p 140.)

fever, hypotension, capillary leakage with decreased intravascular volume, and myocardial depression.²³ More recently, pro-inflammatory cytokines such as macrophage migration inhibitory factor (MIF) and high mobility group 1 protein (HMG-1) have received attention as downstream mediators of inflammation and potential therapeutic targets.²⁴⁻²⁷ The role of anti-inflammatory cytokines in sepsis is still not fully understood. Current understanding suggests that sepsis-induced multiorgan failure and death may be caused in part by a shift to an anti-inflammatory phenotype and by apoptosis of key immune cells.^{28,29} This shift is driven in part by increased levels of anti-inflammatory cytokines and results from a shift in helper T-cell populations (from Th1 to Th2).³⁰ Inflammation plays an important role in the host response to sepsis. It is now apparent that simple therapeutic strategies that block specific pro-inflammatory cytokines are insufficient to modulate this response.^{31,32} As our understanding of the intricate relationship between pro-inflammatory and anti-inflammatory responses increases, we might become more successful in modulating these to improve patients' outcomes.

ALTERATIONS OF HEMOSTASIS

Another important factor in the pathophysiology of sepsis is the alteration of the hemostatic balance. In sepsis this balance is altered by an increase in procoagulant factors paired with a decrease in anticoagulant factors (Fig. 25.2). Under normal conditions the intraluminal vascular surface has anticoagulant properties. During sepsis, stimulation from cytokines promotes expression of tissue factor on endothelial cells, monocytes, and neutrophils.^{33,34} Tissue factor triggers the extrinsic coagulation pathway by activating factor VII. Activation of the extrinsic pathway leads to the formation of thrombin. The intrinsic pathway is triggered by activation of factor XI and leads to amplification of the coagulation cascade with further formation of thrombin. Excessive coagulation is normally counterbalanced by several anticoagulant factors. Anticoagulant factors such as antithrombin III, activated protein C, protein S, and tissue factor pathway inhibitor are decreased in sepsis.³⁵ These circumstances push the hemostatic balance toward the pro-coagulant state. Activation of the coagulation cascade leads

Figure 25.2 Relationship between inflammatory and coagulation systems in sepsis. Monocytes are activated by endotoxins and exotoxins from bacteria and release tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β). TNF- α and IL-1 β activate the inflammatory cascade via neutrophils and the production of other proinflammatory cytokines, and, in combination with tissue factor, they also activate the coagulation cascade, with production of fibrin and fibrin degradation products (FDP). APC, activated protein C. (Adapted from Matthay MA: Severe sepsis: A new treatment with both anticoagulant and anti-inflammatory properties. *N Engl J Med* 2001;344:759-762, Figure 1A, p 761.)

to a consumption of coagulation factors. The clinical expression of this phenomenon is disseminated intravascular coagulation (DIC). Disseminated intravascular coagulation is characterized by a consumptive coagulopathy, which can result in an increased risk of bleeding but more commonly in sepsis causes damage by increasing the risk of thrombosis. In sepsis the excessive formation of fibrin from thrombin compounded by the suppression of fibrinolysis and the impairment of anticoagulant pathways leads to widespread formation of microthrombi. It has been proposed that these microthrombi lead to microcirculatory alterations and play an integral role in the pathogenesis of organ failure.^{36,37}

MANAGEMENT

Severe sepsis is a medical emergency. When one considers its morbidity and the relationship between number of organ failures and mortality (Fig. 25.3), it makes sense to treat patients emergently and institute therapies that can prevent the progression of organ failure and improve outcomes in a time-sensitive fashion. Several therapies for severe sepsis have a potential time-sensitive effect on outcome (e.g., when instituted early have a higher likelihood of improving outcomes than when instituted with time delays) (Box 25.2). Although severe sepsis is associated with a higher mortality than other diseases considered medical emergencies, such as trauma, acute ischemic stroke, and acute myocardial infarction, it is still not treated with the same degree of urgency. This may be secondary to difficulties in recognizing severe sepsis early and a lack of understanding its consequences and their therapeutic implications by physicians outside the intensive care unit.

Recognizing these problems, the Society of Critical Care Medicine (SCCM), the European Society of Intensive Care Medicine (ESICM), and the International Sepsis Forum

Figure 25.3 Relationship between number of organ failures and mortality. As the number of organ failures rises, mortality from severe sepsis progressively increases. With four organ failures, for example, mortality approaches 80%. (Data from Angus D, Linde-Zwirble WT, Clermont G, et al: Epidemiology of neonatal respiratory failure in the United States: Projections from California and New York. *Crit Care Med* 2001;29:1303-1310.)

- Glucose control

(ISF) created the Surviving Sepsis Campaign (SSC). The SSC conglomerates experts in the field of sepsis from around the world and currently counts with the endorsement of 29 international medical societies and the Institute for Healthcare Improvement (www.ihl.gov). The campaign has aimed to improve standards of patient care, secure funding for research, and ultimately reduce the mortality of severe sepsis worldwide. To achieve these goals, the SCC has published evidence-based practice guidelines and consensus recommendations for the management of patients with severe sepsis.^{38,39,39a} These guidelines were first published in 2004 and revised in 2008, and a second revision for 2012 is currently in press. To increase the impact of these clinical guidelines at the bedside, the SCC created the sepsis bundles.⁴⁰ The *sepsis resuscitation bundle* should be implemented over the first 6 hours after recognition of a patient with severe sepsis, and the *sepsis management bundle* should be implemented over the first 24 hours of admission to the hospital. A number of nonrandomized studies have shown that compliance with the bundles and application of their clinical recommendations in the form of protocols can improve patient outcomes.⁴¹⁻⁴³ More important, the publication of phase 2 of the SSC international performance improvement program demonstrated the significant impact compliance with the sepsis bundles has on reducing mortality in severe sepsis.⁴⁴ This large prospective study evaluated the implementation of a multifaceted intervention to facilitate compliance with selected guideline recommendations in the intensive care unit, emergency department, and wards of hospitals from around the world. Data from 15,022

Figure 25.4 Approach to treatment of severe sepsis.

Box 25.3 Sepsis Resuscitation Bundle (to be started immediately and completed within 3 hours)

- Serum lactate measured*
- Blood cultures obtained prior to antibiotic administration
- Minimize time to administration of broad-spectrum antibiotics with a maximum of 3 hours from ED triage and 1 hour for non-ED ICU admissions
- In the event of hypotension or lactate > 4 mmol/L (36 mg/dL) deliver an initial minimum of 30 mL/kg of crystalloid (or colloid equivalent)

*A normal lactate level does not exclude severe sepsis.
ED, emergency department; ICU, intensive care unit.

Box 25.4 Septic Shock Bundle (to be started immediately and completed within 6 hours)

- Apply vasopressors for hypotension that does not respond to initial fluid resuscitation to maintain mean arterial pressure (MAP) \geq 65 mm Hg.
- In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate > 4 mmol/L (36 mg/dL):
 - Achieve a central venous pressure (CVP) of \geq 8 mm Hg.
 - Achieve central venous oxygen saturation (ScvO₂) of \geq 70%.

subjects at 165 sites were analyzed to determine the compliance with bundle targets and association with hospital mortality. Compliance with the entire resuscitation bundle increased from 10.9% to 31.3% by the end of 2 years ($p < 0.0001$). Compliance with the entire management bundle started at 18.4% and increased to 36.1% by the end of 2 years ($p = 0.008$). This increase in compliance was associated with a decrease in unadjusted hospital mortality from 37% to 30.8% ($p = .001$). The adjusted odds ratio for mortality improved the longer the site participated in the SSC.⁴⁴ Based on emerging data and recently published studies, the last revision of the guidelines recommends dropping the management bundle and dividing the resuscitation bundle into two parts:^{39a}

- Initial resuscitation bundle
 - To be initiated immediately upon identifying patients with severe sepsis and septic shock
- Septic shock bundle
 - To be initiated immediately and completed within 6 hours for patients with septic shock

The complete new bundles are shown in Box 25.3 and Box 25.4. The optimal treatment of severe sepsis is a dynamic and constantly evolving process. We will discuss current treatment recommendations based on up-to-date clinical data. However, as new research emerges it is likely that new therapies will be described, and treatment recommendations presented in this chapter may need to be modified.

Like in other medical emergencies the first priority in treating patients with severe sepsis should be assessing and optimizing the “ABCs”: airway, breathing, and circulation. In conjunction with initial stabilization of physiologic abnormalities, one should initiate appropriate diagnostic interventions to assess potential sources of infection and severity

of organ dysfunction. Therapeutic interventions for severe sepsis should be implemented quickly and in conjunction. For the sake of discussion we will approach the treatment of severe sepsis based on pathophysiologic abnormalities produced by the syndrome (Fig. 25.4). We will discuss in further detail management of the infectious insult, hemodynamic optimization, modulation of the host response, and finally supportive therapies.

INFECTION MANAGEMENT

Severe sepsis is initiated by an infectious insult. Therefore, infection management constitutes one of the cornerstones of treatment in these patients. Infection management consists of source control and the administration of appropriate empiric antimicrobials that are effective against presumed causative pathogens. Administration of appropriate antibiotics is a time-sensitive intervention. Administration of antibiotics is often delayed, and this can result in worse outcomes.⁴⁵ Delays in appropriate antibiotic administration are much more likely to result from system failures (e.g., order not written by physician, delay from pharmacy, etc.) than from bacteriologic resistance.⁴⁶ Current guidelines recommend that appropriate antibiotics be administered to patients with severe sepsis within 1 hour of diagnosis.³⁹ Results from a retrospective study in a large group of septic shock patients suggests that every hour appropriate antibiotics are delayed after the onset of hypotension, the odds ratio for mortality increases in a stepwise manner.⁴⁷ Additional studies have shown increased mortality with delays in appropriate antibiotic administration.^{43,44,48,49} One study done in patients in the emergency department showed that if antibiotics were given prior to the onset of shock, mortality was significantly decreased.⁵⁰ However, among patients who received antibiotics after shock recognition, mortality did

not change with hourly delays in antibiotic administration.⁵⁰ The goal should be to administer appropriate antibiotics as soon as possible in patients with severe sepsis. To accomplish this objective, hospitals must examine their particular dynamics and devise systems to optimize antibiotic administration.

Studies in patients with sepsis have reported an incidence of positive blood cultures in the range of 20% to 50%.^{8,51-53} Considering the growing need for broad-spectrum empirical regimens and the need to narrow down antimicrobial regimens in order to decrease resistance, obtaining blood cultures prior to the administration of antibiotics is essential. In most cases, one must start antibiotics without bacteriologic confirmation of the causative pathogen. Studies have demonstrated that the appropriateness of initial antibiotic therapy has a significant impact on patient outcomes.^{54,55} In one prospective cohort study of critically ill patients, inadequate initial antibiotic therapy was associated with a statistically significant increase in all-cause and infection-related hospital mortality.⁵⁶ Factors associated with administration of inadequate antibiotics included prior administration of antibiotics, bloodstream infections, increasing acute physiology and chronic health evaluation (APACHE II) scores, and decreasing age.⁵⁶ If one considers the detrimental effect on mortality, it is apparent that in patients with severe sepsis, one cannot afford to miss potential causative organisms when empirically selecting an antimicrobial regimen. The choice of antibiotics should be based on the following factors:

- Probable pathogens based on clinical diagnosis and source of infection (pneumonia, bloodstream infection, abdominal source, etc.)
- Site where infection was acquired (community versus hospital acquired)
- Results obtained from diagnostic tests such as Gram stains
- Resistance patterns of local and hospital bacterial flora
- Patient comorbidities, drug allergies, and previous antibiotic exposure

Initial empiric anti-infective therapy should include one or more drugs that have activity against likely pathogens and that penetrate the presumptive site of infection in adequate concentrations. Recently used anti-infective drugs in a particular patient should be avoided as the likelihood of resistance increases. Clinicians should also consider whether candidemia is a likely pathogen based on the presence of predisposing risk factors. When indicated, empirical antifungal therapy should take into account local flora and previous exposure of the patient to azole drugs. Recent Infectious Disease Society of America (IDSA) guidelines recommend either fluconazole or an echinocandin.⁵⁷ Empiric use of echinocandin is preferred in critically ill patients, those exposed to azole drugs, and in settings where infection with *C. glabrata* is suspected or documented. Initial antibiotic therapy for severe sepsis should be broad in spectrum and progressively narrowed as microbiologic data become available. In culture-negative patients, the de-escalation of antibiotics may become challenging. In these cases, clinical evolution can be used to guide decisions. A detailed discussion of specific antibiotic regimens is beyond the scope of this chapter; the reader is referred

to other chapters in the textbook and to the synopsis in Table 25.3.

The term *source control* refers to measures implemented to control the source of infection. Source control interventions can be divided into three broad categories: (1) drainage of an abscess, (2) debridement/drainage/incision of infected tissue, and (3) removal of an infected foreign body.⁵⁸ Attention to identifying potential sources amenable to source control measures should be part of the initial evaluation of patients with sepsis. The timing of intervention depends on several factors. When source interventions are simple, such as removal of an infected central venous catheter, they should be implemented immediately. In cases of unstable patients where surgery might be required, delaying source control while optimizing hemodynamic status may be appropriate. Finally, in cases such as necrotizing fasciitis, in which delays carry a significant risk of increasing mortality, one must proceed to surgery as early as possible. Examples of specific source control measures in patients with sepsis are shown on Table 25.4.

HEMODYNAMIC OPTIMIZATION

Severe sepsis is associated with a host of hemodynamic abnormalities. These abnormalities can ultimately lead to sepsis-induced tissue hypoperfusion if not addressed early and aggressively. The hemodynamic profile of severe sepsis and septic shock is initially characterized by components of hypovolemic, cardiogenic, and distributive shock.⁵⁹ In the initial phases of resuscitation, addressing the hypovolemic component is most important. Early in sepsis, increased capillary leak and increased venous capacitance will result in effective hypovolemia with decreased venous return to the heart. Low intravascular volume paired with sepsis-induced myocardial depression will result in a decrease in stroke volume (SV). Administration of intravascular fluids can alter this early phase of sepsis characterized by hypovolemia, tachycardia, and depressed cardiac output. Initial steps in hemodynamic optimization for patients with severe sepsis should include evaluation for signs of sepsis-induced tissue hypoperfusion. Signs of global hypoperfusion such as hypotension, tachycardia, oliguria, delayed capillary refill, altered mentation, increased blood lactate, and low mixed venous oxygen saturation are helpful when present to establish tissue hypoperfusion. However, these signs are not always sensitive and they must be complemented with assessment of indices of regional hypoperfusion. Patients with severe sepsis should have good venous access. Central venous access is preferred as it can also be used for hemodynamic monitoring.

The importance of early intervention in patients with sepsis-induced tissue hypoperfusion has been highlighted by the results of an early goal-directed therapy (EGDT) clinical trial by Rivers and colleagues.⁶⁰ In this study, patients with sepsis-induced hypoperfusion (lactate > 4 mmol or hypotension after fluids) were randomized to receive either standard resuscitation or an early goal-directed (EGDT) protocol during the first 6 hours of admission to the emergency department. In both groups, end points of resuscitation included central venous pressure (CVP) ≥ 8 to 12 mm Hg, mean arterial pressure (MAP) ≥ 65 mm Hg, and urine output ≥ 0.5 mL/kg/hr. To achieve these goals,

Table 25.3 Antibiotic Selection for Sepsis Based on Site of Infection

Site	Bacteria	First-Line Agent	Second-Line Agent
Abdominal			
Primary peritonitis	Enterobacteriaceae <i>S. pneumoniae</i> <i>Enterococcus faecalis</i>	Third-generation cephalosporins: —Cefotaxime —Ceftriaxone	Quinolones Imipenem-cilastatin Piperacillin-tazobactam

patients were treated with intravenous crystalloids and vasopressors. The EGDT group had as an additional end point, central venous oxygen saturation ($ScvO_2$) $\geq 70\%$, which was continuously measured from a subclavian or jugular central venous catheter. $ScvO_2$ was used as an index for oxygen delivery. If $ScvO_2$ was $< 70\%$ after reaching targets for CVP and MAP, patients received packed red blood cells for a hematocrit ≤ 30 , or dobutamine infusion if the hematocrit was ≥ 30 . Patients in the EGDT group received more fluids, dobutamine, and transfusions in the first 24 hours. In-hospital mortality was significantly lower in the EGDT group when compared to the standard therapy group (30.5% versus 46.5%, respectively, [$p = 0.009$]). Observational studies published after the Rivers study have demonstrated a strong association between improved clinical outcomes and maintenance of MAP ≥ 65 mm Hg as well as central venous oxygen saturation ($ScvO_2$) of $\geq 70\%$.⁶¹ Furthermore, several more recent studies have showed improved outcomes with the use of protocolized quantitative resuscitation in severe sepsis and sepsis-induced tissue hypoperfusion.^{42,62-65} Although the specific merits of each individual

intervention within a quantitative resuscitation or EGD^T protocol can be discussed, the results of these studies strongly support early intervention with predefined hemodynamic settings and protocolized care.

As stated before, the initial step in optimizing hemodynamics in patients with severe sepsis is aggressive fluid resuscitation. Although experts agree on the value of early and aggressive volume replacement, controversy persists over the optimal type of fluid. This debate revolves around the use of crystalloids (saline, Ringer's lactate) versus colloids (albumin, hydroxyethyl starches). A large meta-analysis evaluated data from 56 trials and found no difference in mortality between crystalloids and colloids when used for initial fluid resuscitation.⁶⁶ Three randomized studies did not find a difference in mortality when starches (heta-, hexa-, or penta-) were compared to other fluids. However, these studies did report a significant increase in acute kidney injury with the use of starches.⁶⁷⁻⁶⁹ The Saline versus Albumin Fluid Evaluation (SAFE) study prospectively randomized 7000 critically ill patients to receive 4% albumin or 0.9% saline for fluid resuscitation.⁷⁰ There were no significant differences between groups in mortality and other secondary outcomes. A subgroup analysis conducted in patients with sepsis revealed a trend toward improved outcomes in patients treated with albumin, although this difference did not achieve statistical significance. We believe that achieving end points of resuscitation is more important than the type of fluid utilized. In North America consideration for cost differences has made crystalloids the initial fluid of choice for resuscitating patients with severe sepsis. However, based on emerging data it seems appropriate to add albumin to the initial fluid resuscitation regimen in severe sepsis and septic shock.

Patients with severe sepsis may present with significant intravascular volume depletion. Aggressive fluid boluses are usually required to restore tissue perfusion. It is recommended that patients receive at least 20 to 30 mL/kg of crystalloid initially.^{39,71} This may be supplemented with more fluids based on markers of perfusion in repeated boluses of 300 to 500 mL.⁷¹ Current guidelines recommend achieving

the following hemodynamic end points of resuscitation during the first 6 hours of treatment: CVP \geq 8 to 12 mm Hg, mean arterial pressure (MAP) \geq 65 mm Hg, urine output \geq 0.5 mL/kg/h, and central venous oxygen saturation (ScvO₂) \geq 70%.^{39,72} For further discussion on the pathophysiology and treatment of hemodynamic abnormalities in sepsis, the reader is referred to Chapter 23.

MODULATION OF THE HOST RESPONSE

Over the years, research efforts in severe sepsis have been heavily involved with therapies targeted at modulating the host response. Several pathways and mechanisms have been studied in clinical trials (Table 25.5). Unfortunately, very little success has been found in these endeavors. Initial attempts were aimed at blunting the inflammatory response with nonspecific agents such as high-dose glucocorticoids and ibuprofen.⁷³⁻⁷⁵ Another unsuccessful strategy involved the use of antibodies directed at endotoxin in patients with gram-negative sepsis.⁷⁶⁻⁸¹ However, the area that received the greatest attention was modulation of the inflammatory cascade by targeting specific pro-inflammatory cytokines such as tumor necrosis factor (TNF- α) and interleukin-1 β (IL-1 β). Multiple clinical trials enrolling thousands of patients tested compounds directed at specific pro-inflammatory cytokines, among them TNF monoclonal antibody, interleukin-1 receptor antagonist, and soluble TNF receptor.⁸²⁻⁸⁹ Unfortunately, none of these compounds improved survival of patients with severe sepsis in randomized studies. The failure of these therapies led to a reappraisal of the pathophysiology, potential therapeutic targets, and clinical trial design in severe sepsis. As the role of the coagulation cascade and its crosstalk with inflammation in sepsis was recognized, a series of new clinical trials took place. Three large trials studied the effects of anticoagulants in severe sepsis (Box 25.5).

Antithrombin III (AT III) is a progressive inhibitor of thrombin and factor Xa.⁹⁰ Studies showed that AT III supplementation attenuated the systemic inflammatory response in patients with severe sepsis.⁹¹ A large (n = 2314)

Table 25.5 Pathways and Mediators of Sepsis, Potential Treatments, and Results of Randomized, Controlled Trials (RCTs)*

Pathway	Mediators	Treatment	Results of RCTs
Proinflammatory pathway	Lipopolysaccharide (endotoxin)	Antilipopolysaccharide ⁹	Negative
	TNF- α	Anti-TNF- α ^{13,14}	Negative

multicenter, double-blinded, placebo-controlled trial evaluated the safety and efficacy of AT III in adult patients with severe sepsis.⁹² At 28 days there was no difference in mortality between the treatment group and the placebo group (38.9% versus 38.7%, respectively). Patients who received AT III had a higher risk of bleeding (relative risk > 1.7). A subgroup analysis of patients not receiving concomitant heparin showed a trend (statistically nonsignificant) toward reduced mortality at 28 and 90 days with AT III. This specific subgroup of patients with severe sepsis may warrant further investigations. Tissue factor pathway inhibitor (TFPI) has been shown to modulate the extrinsic pathway in preclinical models of severe sepsis. Recombinant human TFPI (tifacogin) was evaluated in clinical trials of patients with severe sepsis. Although the results of a phase II trial suggested a trend toward improved mortality, a large phase III trial, the OPTIMIST (Optimized Phase III Tifacogin in Multicenter International Sepsis Trial) study failed to show a mortality benefit in patients treated with this compound.^{93,94} Patients treated with tifacogin had a higher risk of bleeding complications irrespective of their baseline international normalized ratios (INRs).⁹³ Studies evaluating different dosing regimens and the application of this drug in patients with pneumonia are still being conducted. Finally, recombinant human activated protein C (rhAPC) was evaluated in clinical trials. A landmark study, the protein C worldwide evaluation in severe sepsis (PROWESS) trial, demonstrated improved 28-day survival in patients with severe sepsis treated with rhAPC.⁹⁵

The phase III randomized, double-blind, placebo-controlled, multicenter international study, PROWESS trial evaluated the efficacy of drotrecogin alfa (activated) in patients with severe sepsis.⁹⁵ This study enrolled 1690 patients and was terminated early after an interim safety analysis found a significant reduction in mortality in the treatment group compared to placebo (24.7% versus 30.8%, respectively [$p = 0.005$], relative and absolute risk reductions of 19.4% and 6.1%, respectively). Patients treated with drotrecogin alfa (activated) showed a trend toward a higher incidence of bleeding (3.5% versus 2%; $p = 0.06$). Subgroup analysis demonstrated that patients at higher risk of death as measured by APACHE II scores (APACHE II ≥ 25) and number of organ failures (two or more organ failures) had an increased benefit from the drug. Effects on mortality seemed to be lost in low-severity patients. Based on this study, the Food and Drug Administration (FDA) approved the use of drotrecogin alfa (activated) in adult patients with severe sepsis with a high risk of death. Angus and colleagues reported, after long-term follow-up, that those patients who were treated with drotrecogin alfa (activated) had an

increased median survival (9 months) compared to patients treated with placebo.⁹⁶ Once again, beneficial effects of the drug seemed to be greatest in patients with a higher severity of disease. Two additional phase IV studies were published post the FDA's approval of the drug. The ENHANCE trial was a single-arm open-label study that enrolled 2375 patients with severe sepsis.⁹⁷ ENHANCE evaluated the use of drotrecogin alfa (activated) in a more routine clinical setting beyond the restrictions of a controlled randomized study. In this study, the effect of the drug on mortality was similar to PROWESS (25.3% in ENHANCE versus 24.7% in PROWESS). The risk of bleeding during infusion was higher when compared to PROWESS (3.6% versus 2.4%). However, the higher rate of postinfusion bleeding observed in the ENHANCE population (3.2% versus 1.2%) suggests a higher incidence of background bleeding. A second phase IV trial, the ADDRESS study, was a randomized, blinded, placebo-controlled trial that evaluated the efficacy of the drug in severe sepsis in patients judged prospectively by the enrolling clinician to have a low risk of death (APACHE II score < 25 or single organ failure based on regulation requirements in countries of study entry).⁹⁸ This study enrolled 2646 patients and found that treatment with the drug offered no mortality benefit when compared to placebo in a low-risk-of-death population. Serious bleeding events were similar to those reported in PROWESS. There was significant criticism from several academic experts on the approval of drotrecogin alfa (activated) based on one single positive prospective randomized trial that was terminated prematurely because of positive results. Additionally critics argued that the drug was associated with a higher risk of bleeding when used in the clinical setting and that it was approved for a population that had not been prospectively evaluated in randomized trials (based on the post hoc analysis of the APACHE II quartiles). The publication of the PROWESS SHOCK trial, showing no benefit of drotrecogin alfa (activated) in patients with septic shock (mortality 26.4% in patients given drotrecogin alfa [activated] versus 24.2% in patients receiving placebo) led to the worldwide withdrawal of the drug from the market.⁹⁹ The choice to withdraw was a voluntary decision by Eli Lilly and Company and was likely heavily influenced by business calculations. Drotrecogin alfa (activated) has important biologic effects that could be helpful in modulating the host response in severe sepsis. It is very probable that we do not know how best to select patients who would benefit from this drug. In the future, we should consider ways to improve our process in drug development from clinical trial design to regulatory approval. Furthermore, it seems that more sophisticated selection of patients will be instrumental in future studies evaluating new agents designed to modulate the host response to sepsis.¹⁰⁰

SUPPORTIVE THERAPIES

As with other critical illnesses, patients with severe sepsis require various supportive therapies (see Box 25.5). These therapies are general supportive measures that prevent complications associated with critical illness. Improvement in these therapies over the years probably plays a role in the historical decrease in mortality observed in several disease processes such as severe sepsis and acute

respiratory distress syndrome (ARDS). Patients with severe sepsis often present with tachypnea and hypoxemia. Mechanical ventilation is often utilized for support. Studies in patients with ARDS have demonstrated that ventilation strategies utilizing low tidal volume (6 mL/kg) are associated with significantly lower mortality than ventilation with more traditional tidal volumes (12 mL/kg).¹⁰¹ This is most likely due to a decrease in ventilator-induced lung injury. Several meta-analyses have suggest decreased mortality in patients with established ARDS who are treated with a volume and pressure limited ventilator strategy.^{102,103} Current guidelines recommend the use of a protective lung strategy (low tidal volume; inspiratory plateau pressure < 30 cm H₂O) in mechanically ventilated patients with severe sepsis.³⁹ Goals for oxygen saturation should be an $\text{Sao}_2 \geq 90\%$. This can be achieved by increasing the fraction of inspired oxygen (Fio_2) and/or application of positive end-expiratory pressure (PEEP). In patients with sepsis-induced ARDS who do not have evidence of tissue hypoperfusion, a conservative approach to fluid management is recommended.¹⁰⁴ Patients on mechanical ventilation who are clinically improving should be evaluated on a daily basis for weaning from mechanical ventilation. Patients with severe sepsis on mechanical ventilation should be managed with appropriate sedatives and analgesics. For a detailed discussion, the reader is referred to Chapter 19.

Patients with severe sepsis should receive prophylaxis for the development of deep vein thrombosis (DVT). In the absence of contraindications, patients should receive pharmacologic DVT prophylaxis. Treatment with low-dose unfractionated heparin (UFH), adjusted-dose UFH, or low-molecular-weight heparin (LMWH) is recommended.¹⁰⁵ Treatment for DVT prophylaxis with UFH or LMWH is not contraindicated during infusion of drotrecogin alfa (activated). Stress ulcer prophylaxis is recommended for all patients with severe sepsis. Histamine-2 receptor antagonists are more effective than sucralfate in decreasing bleeding risk and transfusion requirements.¹⁰⁶ Proton pump inhibitors have not been assessed in a direct comparison with histamine-2 receptor antagonists but do demonstrate equivalence and ability to increase gastric pH.¹⁰⁵

Severe sepsis is a catabolic state. Metabolic alterations in patients with severe sepsis include breakdown of proteins, carbohydrates, and lipids; negative nitrogen balance; and hyperglycemia with insulin resistance. As with other critically ill patients, those with severe sepsis require adequate nutritional support. Enteral nutrition offers several advantages including lower cost, preservation of gastric mucosa integrity, decreased incidence of infections, and avoidance of parenteral nutritional catheters and their potential complications.¹⁰⁷ In patients who cannot tolerate enteral nutrition, parenteral nutrition should be utilized.¹⁰⁸ Immunomodulation through nutritional supplements has been proposed in patients with severe sepsis but remains experimental at this point.

Hyperglycemia and insulin resistance are commonly present in patients with severe sepsis. This phenomenon is a common feature of the metabolic response to critical illness and stress and has been described after major surgery, in trauma, acute myocardial infarction, and several other disease states. Furthermore, there is a growing body of literature suggesting that hyperglycemia related to critical

illness is associated with poor outcomes.¹⁰⁹⁻¹¹³ Proposed mechanisms for this deleterious effect include impaired neutrophil function, increased risk of infection, poor wound healing, and procoagulant state as a consequence of hyperglycemia.¹¹⁴ Treatment of critical illness-related hyperglycemia with insulin has been proposed to modulate these effects and improve patient outcomes. Van den Berghe and associates studied the effects of tight glycemic control on outcomes in a population of mechanically ventilated surgical critical care patients.¹¹⁵ In this study, patients were randomized to receive intensive insulin therapy (target blood glucose 80-110 mg/dL) or standard therapy (target blood glucose 180-200 mg/dL). Patients treated with the intensive insulin regimen had significant improvements in overall ICU mortality rates (4.6% versus 8.0%). This benefit in mortality was more pronounced among patients who stayed in the ICU longer than 5 days (10.6% versus 20.2%, $p = 0.005$). In addition, intensive insulin therapy was associated with a 46% reduction in bloodstream infections, a 44% reduction in the incidence of critical illness polyneuropathy, a 41% decrease in the need for renal replacement therapy, and a 50% reduction in number of transfused units of packed red blood cells. The same group reported the results of a similar study in medical intensive care unit patients.¹¹⁶ In this clinical trial, intensive insulin was not associated with improved mortality when compared to standard therapy. Intensive insulin therapy was associated with decreased mortality in patients who remained in the ICU > 3 days, but it was associated with increased mortality in those who remained in the ICU < 3 days. Prospective identification of these patient groups was difficult. Studies published more recently have not found the same benefit in mortality with intensive insulin therapy.^{69,117-119} The NICE-SUGAR study, a large randomized trial with > 6000 patients, found that intensive glucose control increased mortality among adults in the ICU.¹²⁰ In this study, a blood glucose target of 180 mg or less/dL resulted in lower mortality than did a target of 81 to 108 mg per deciliter.¹²⁰ Two questions remain germane to the glycemic control issue: First, what is the downside of tight glycemic control? Second, what level of glucose should we target? The biggest downside to tight glycemic control probably relates to the risk of hypoglycemia and the morbidity/mortality this could cause in critically ill patients. In both studies by Van den Berghe and colleagues, hypoglycemia was more common in the intensive insulin group than in the standard group (surgical study: 5.2% versus 0.7% and medical study: 18.7% versus 3.1%, respectively).^{115,116} In subsequent studies, the incidence of hypoglycemia was consistently higher. As an example in the NICE-SUGAR study, severe hypoglycemia (blood glucose level, ≤ 40 mg/dL) was reported in 6.8% of the patients in the intensive-control group and in 0.5% of the patients in the conventional-control group ($p < 0.001$).¹²⁰ Concerns for the effects of hypoglycemia on ICU patients are well founded. However, it does not appear that short-term hypoglycemia that is quickly recognized and treated carries deleterious consequences.¹²¹ There is no clear answer with respect to what glucose level we should target in patients with severe sepsis. It is important to note that the studies that showed benefit with tight glycemic control compared intensive insulin therapy to high controls (180-200 mg/dL), whereas those that did not demonstrate benefit compared

Figure 25.5 Identification of organ failure in severe sepsis. Clinical and laboratory criteria to identify organ failure are shown for each organ system. APTT, activated partial thromboplastin time; CNS, central nervous system; CVP, central venous pressure; PAOP, pulmonary artery occlusion pressure; PT, prothrombin time. (Adapted from Balk RA: Pathogenesis and management of multiple organ dysfunction or failure in severe sepsis and septic shock. *Crit Care Clin* 2000;16:337-352.)

intensive insulin therapy to moderate controls (108-180 mg/dL). Considering the current available evidence, it is recommended that glucose be kept $< 180 \text{ mg/dL}$ in patients with severe sepsis. To minimize the risk of hypoglycemia, patients on intensive insulin regimens should have frequent blood glucose monitoring.

MULTIPLE ORGAN DYSFUNCTION

Multiple organ dysfunction is a common complication of sepsis. Multiple organ dysfunction syndrome (MODS) occurs when two or more organ systems fail sequentially or at the same time in a patient with sepsis. Various organs, such as the brain, heart, lung, kidney, and liver, can be affected in patients with severe sepsis. Often these organs are distant from the site of primary insult, and development of organ failure occurs as a response to complicated interactions and pathophysiologic events. Metabolic and hematologic dysfunctions are also common with severe sepsis and MODS. MODS significantly contributes to higher mortality. Studies have shown that mortality in patients with severe sepsis increases in parallel with increases in number and severity of organ failures.^{122,123} Russell and associates evaluated the pattern of organ dysfunction in early sepsis and its relationship with mortality.¹²⁴ In this study, clinically significant pulmonary dysfunction, although common early in sepsis, was not associated with 30-day mortality. Early dysfunction of other organs and, particularly, worsening neurologic, coagulation, and renal dysfunction over the first 3 days were associated with significantly higher 30-day mortality.

Recognition of early organ dysfunction is important because it is likely that early intervention can affect outcomes. The clinical manifestations of MODS for individual organs are summarized in [Figure 25.5](#). The cornerstones of treatment for MODS are based on appropriate treatment for the underlying cause (sepsis) and on early organ-specific support interventions. As discussed previously, early implementation of therapies directed at control of infection, hemodynamic support, and modulation of the host response are key to improving organ dysfunction and patient outcomes. Perhaps the single most important aspect relates to early and aggressive hemodynamic support. As demonstrated in the study by Rivers and colleagues, goal-directed interventions instituted in the first 6 hours of presentation to the hospital have a tremendous impact on long-term organ function and survival.⁶⁰ We further discuss some salient features of the pathophysiology of MODS and the use of scoring systems. For a more detailed discussion on organ-specific supportive therapies, the reader is referred to other chapters in this textbook.

PATHOPHYSIOLOGY OF MULTIPLE ORGAN DYSFUNCTION SYNDROME IN SEPSIS

The mechanisms that result in the development of MODS in patients with sepsis are still not fully understood. Additionally, the reason that some patients develop MODS and others do not remains unknown. However, new insights into the pathophysiology of severe sepsis have led to a better understanding of potential mechanisms leading to MODS. In patients in whom MODS develops, the host response to infection becomes sustained and uncontrolled, leading to a complex interaction of inflammatory, anti-inflammatory,

and procoagulant cascades culminating in the development of organ failure. A key determinant of organ failure seems to be tissue hypoperfusion. Our current knowledge seems to point out two important mechanisms in the development of sepsis-induced tissue hypoperfusion: microvascular dysfunction and cytopathic hypoxia.

In early unresuscitated sepsis, tissue hypoperfusion is to a great extent driven by decreased intravascular volume and the resulting drop in cardiac output (hypovolemic shock).⁵⁴ Despite aggressive volume resuscitation, however, many patients still show evidence of tissue hypoperfusion, probably secondary to vasodilation and maldistribution of blood flow (distributive shock).⁷¹ Furthermore, a subset of patients with normalized macrovascular hemodynamic parameters (e.g., blood pressure, CVP, and cardiac output) can still show evidence of sepsis-induced tissue hypoperfusion.¹²⁵ New technology has allowed investigators to evaluate the microcirculatory flow in patients with severe sepsis.¹²⁶ Redistribution of capillary blood flow has been demonstrated in both animal models and clinical sepsis.^{36,37} The importance of this finding has been highlighted by studies demonstrating that functional (impaired blood flow) and structural (shunting, redistribution) abnormalities in microcirculation are associated with death and organ failure in patients with severe sepsis and septic shock.^{37,127}

In the early phases of sepsis, decreased oxygen delivery (DO_2) can result in tissue hypoperfusion. However, in late sepsis there is evidence of impaired tissue oxygen utilization even after optimization of DO_2 .¹²⁸ The inability of cells to use oxygen in the face of adequate DO_2 in sepsis has been termed *cytopathic hypoxia*.¹²⁸ Development of cytopathic hypoxia is closely linked to mitochondrial dysfunction. The inability of the mitochondria to use oxygen to produce energy in the form of adenosine triphosphate leads to impaired cellular function. Proposed mechanisms that result in cytopathic hypoxia in sepsis include diminished delivery of pyruvate into the mitochondria, inhibition of mitochondrial enzymes, and activation of poly-(adenosine phosphate-ribosyl) polymerase (PARP).¹²⁹ The exact mechanisms leading to organ failure in sepsis remain

unidentified. Organ failure in sepsis is reversible in patients who survive. Furthermore, in patients who do not survive, there is no histopathologic evidence of tissue damage.²⁸ Hotchkiss and associates have described extensive lymphocyte apoptosis in sepsis and have proposed this mechanism as an important driver of the impaired immune response seen in late sepsis and MODS.^{130,131} Finally, multiple organ failure has been hypothesized to be an adaptive metabolic response to overwhelming inflammation in sepsis.¹³² The hypothesis holds that multiple organ failure induced by sepsis is primarily a functional abnormality that serves as a protective reactive mechanism and that the decline of organ function is triggered by a decrease in mitochondrial activity. This decrease in mitochondrial activity leads to a reduction in cell metabolism and occurs as a consequence of humoral and mediator-induced changes.¹¹⁸

ORGAN DYSFUNCTION SCORING SYSTEMS

Severity of illness scoring systems have been developed and applied in the ICU to describe patient populations. These scoring systems have been useful in predicting expected mortality and comparing different patient populations. The use of general outcome prediction models, such as the APACHE, the Mortality Probability Model (MPM), and the second Simplified Acute Physiologic Score (SAPS), is discussed in detail in Chapter 74. Therefore, this discussion is limited to scoring systems used to specifically assess organ dysfunction.

It is recognized that the risk of death for patients with severe sepsis is directly related to the number of dysfunctional organs. Organ dysfunction scoring systems have been developed as a tool for the clinician to characterize the severity of illness and follow the clinical evolution of patients with sepsis. The more commonly used systems are the Sequential Organ Failure Assessment (SOFA), the Logistic Organ Dysfunction System, and the Multiple Organ Dysfunction Score. Perhaps the most commonly used is the SOFA score (Table 25.6). It was initially described by Vincent and colleagues to assess the incidence of organ dysfunction

Table 25.6 The Sequential Organ Failure Assessment Score

	0	1	2	3	4
Respiratory: $\text{PaO}_2/\text{FiO}_2$ ratio	> 400	≤ 400	≤ 300	$\leq 200^\circ$	$\leq 100^\circ$
Coagulation: platelets ($\times 10^3 \mu\text{L}^{-1}$)	> 150	≤ 150	≤ 100	≤ 50	≤ 20
Liver: bilirubin (mg dL^{-1})	< 1.2	1.2-1.9	2-5.9	6-11.9	> 12
Cardiovascular: hypotension	No hypotension	MAP < 70 mm Hg	Dop ≤ 5 or Dob any dose	Dop > 5, Epi ≤ 0.1 or Nor ≤ 0.1	Dop ≥ 50 , Epi > 0.1 or Nor > 0.1
Central nervous system: GCS	15	13-14	10-12	6-9	< 6
Renal: creatinine (mg dL^{-1}) or daily urine output (mL)	< 1.2	1.2-1.9	2-3.4	3.5-4.9 or < 500	> 5 or < 200

MAP, mean arterial blood pressure; Nor, norepinephrine; Dop, dopamine; Dob, dobutamine; Epi, epinephrine; FiO_2 , fraction of inspired oxygen; GCS, Glasgow Coma Scale score.

Adapted from Vincent JL, de Mendonca A, Cantraine F, et al: Use of the SOFA score to assess the incidence of organ dysfunction/failure in intensive care units: Results of a multicenter, prospective study. Working group on "sepsis-related problems" of the European Society of Intensive Care Medicine. *Crit Care Med* 1998;26:1793-1800.

in critically ill patients.¹²³ Using the SOFA scores in patients with severe sepsis, these researchers found that mortality rates were lowest in patients without organ dysfunction (9%) and rose progressively with the number of organ dysfunctions (one organ, 22%; two organs, 38%; three organs, 69%; \geq four organs, 83%).¹²³ The type of organ dysfunction also affects mortality. Hebert and coworkers¹⁰⁶ used logistic regression analysis of the results of a simple multiple system organ failure score to determine the odds ratio for death for specific organ system dysfunctions. This study showed that the adjusted odds ratios (OR) for covariates most predictive of mortality were hematologic (OR = 6.2), neurologic (OR = 4.4), hepatic (OR = 3.4), cardiovascular (OR = 2.6), and age (OR = 1.05). It is important to remember that there are caveats when employing organ dysfunction scores for the management of individual patients with severe sepsis. Most important, organ dysfunction is not a static process and it changes over time. Levy and colleagues reported that changes in SOFA score over the first 24 hours were associated with outcomes in patients with severe sepsis. Improvement in cardiovascular, renal, or respiratory failure over the first 24 hours was associated with lower mortality.¹³³ On the other hand, worsening SOFA scores for these organ systems were associated with higher mortality (an approximately 60% mortality rate). Finally, how these scores change over time in response to therapeutic interventions is probably of greater value than an initial organ dysfunction score.

KEY POINTS

- Sepsis is the result of a systemic inflammatory response to infection. Severe sepsis is defined as sepsis with organ failure.
- The pathophysiology of severe sepsis is complex and involves alterations in the immune system, the inflammatory response, and the coagulation cascade.
- Severe sepsis is common and is associated with high morbidity and mortality.
- Severe sepsis is a medical emergency. Institution of time-sensitive therapeutic interventions is a key factor in modulating and improving outcomes.
- The cornerstones for treatment of sepsis are management of the infection, hemodynamic support, modulation of the host response, and general supportive care.
- Infection management includes the early administration of appropriate antibiotics and institution of source control measures.

KEY POINTS (Continued)

- Hemodynamic support consists of early and aggressive fluid resuscitation and maintenance of predefined hemodynamic end points. Studies have shown that early goal-directed therapy for hemodynamic support can improve mortality in patients with severe sepsis.
- To maximize patient outcomes, appropriate supportive therapy must be provided in the ICU: protective lung ventilation, proper nutrition, prophylaxis against DVT, and glucose control.
- Multiple organ dysfunction syndrome (MODS) occurs when failure of two or more organs develops in a patient with severe sepsis.
- Treatment of MODS is based on treatment of the underlying insult and organ-specific supportive measures.

COMPLICATIONS AND PROGNOSIS

CONCLUSION

Although hypovolemic shock has been recognized for more than 100 years, Wiggers¹ in 1940 first offered a definition of hypovolemic shock that has remained significant until now: “Shock is a syndrome resulting from depression of many functions, but in which the reduction of the effective circulating blood volume is of basic importance, and in which impairment of the circulation steadily progresses until it eventuates in a state of irreversible circulatory failure.” Today, hypovolemic shock can be defined as an acute disturbance in the circulation leading to an imbalance between oxygen supply and demand in the tissues, caused by a decrease in circulating blood volume, mostly caused by trauma and hemorrhage.² An oxygen debt develops when uptake no longer matches the demand for oxygen and leads to cellular ischemia and ultimately cell death. The condition is life threatening and, if left untreated, becomes irreversible after a certain period. Rapid and adequate resuscitation is mandatory to save lives. Conversely, hypovolemic shock carries a relatively favorable prognosis, if rapidly and adequately recognized and treated.

Hypovolemic shock can occur outside and inside the hospital, in trauma or surgery complicated by excessive loss of blood, but also in the course of burns, gastrointestinal hemorrhage, diarrhea, uncontrolled diabetes mellitus, Addisonian crisis, and other conditions (Box 26.1). Some other types of shock, including septic, anaphylactoid, cardiogenic, and burn shock, may be accompanied by hypovolemia. The types of shock not primarily caused by hypovolemia are beyond the scope of this chapter.

PATHOGENESIS AND PATHOPHYSIOLOGY

During hypovolemic shock, the loss of circulating blood volume amounts to 15% to 80%. Hypotension ensues when this loss exceeds about 40% and is thus a relatively late and insensitive symptom. The prior hydration status, severity and type of injury, coagulation status, and resuscitation efforts determine the amount of blood lost after trauma. The severity of shock is determined mainly by the speed, duration, and severity of the loss of circulating volume. The pathophysiology of hypovolemic shock concerns primary events, directly relating to the loss of circulating blood volume, and secondary mechanisms, evoked to compensate for this decline, and concerns all components of the circulation. The factors are dealt with together in a general discussion and in a more focused discussion on tissue and organ perfusion and function during hypovolemic shock.

CIRCULATORY CHANGES

GENERAL CHANGES

Because hypovolemia results in a decrease in preload of the heart and low filling pressures or volumes, the cardiac output decreases.³⁻⁹ After unloading of the baroreceptor and activation of the sympathetic nervous system, tachycardia ensues, although some patients may respond with transient sympathetic inhibition and vagal nerve-mediated

Box 26.1 Causes of Hypovolemic Shock**Loss of Blood**

Internally—rupture of vessels, spleen, liver; extrauterine pregnancy

Externally—trauma; gastrointestinal, pulmonary, uterine, renal blood loss

Loss of Plasma

Burn wounds; gastrointestinal losses (diarrhea, ileus, pancreatitis)

Loss of Fluids and Electrolytes

Gastrointestinal and renal losses (uncontrolled diabetes mellitus, adrenocortical insufficiency)

bradycardia during a sudden, severe loss of circulating blood volume.^{3,10-16} Tachycardia partially compensates for the decrease in stroke volume. A moderate decrease in cardiac output can be recognized from a decline in pulse pressure, orthostatic hypotension, and fall in regional perfusion indices.^{8,17,18} Hypovolemia results in wider than usual swings in central venous pressure (CVP) and arterial blood pressure during the respiratory cycle of spontaneous and mechanical ventilation because of increased sensitivity of the underfilled heart in the ascending part of the cardiac function curve to fluctuations in venous return associated with varying intrathoracic pressure.^{19,20} Although activation of the sympathetic nervous system and resulting arterial vasoconstriction during a moderate decrease in cardiac output prevent a severe reduction in arterial blood pressure, a further decrease in cardiac output leads to hypotension and shock.^{8,10} Systemic vascular resistance increases early after development of hypovolemic shock but may decrease in the later stages of shock, and this may herald irreversibility and death. The increase in resistance (and heart rate) may be transiently attenuated after an imbalance between sympathetic and vagal activity, possibly associated with release of opioids within the central nervous system and into the systemic circulation.*

Shock is characterized by an oxygen debt in the tissues.^{9,24-26} In the presence of sufficient oxygen, aerobic combustion of 1 mol of glucose yields 38 mol of energy-rich adenosine triphosphate (ATP), which can be hydrolyzed to provide energy for the vital and metabolic functions of the cell.²⁷ In the absence of oxygen, glucose taken up by cells cannot be combusted because of insufficient uptake of pyruvate into the mitochondrial tricarboxylic acid cycle having a reduced turnover rate. Partly inactivated pyruvate dehydrogenase may play a role in the latter reductions. Pyruvate is converted into lactate, and the lactate-to-pyruvate ratio increases, concomitantly with a reduction in mitochondrial redox potential.^{24,27-29}

Anaerobic glycolysis in the cytosol ultimately yields, per mol of glucose, 2 mol of ATP.²⁷ Hydrolysis of ATP yields hydrogen ions (H⁺) that lead, when buffers are exhausted, to intracellular and ultimately to extracellular metabolic acidosis.³⁰ These mechanisms form the basis of the so-called

lactic acidosis during hypovolemic shock, whereby the lactate level in arterial blood is elevated above the normal 2 mmol/L associated with acidosis, and constitutes a useful measure of the oxygen debt in the tissues.^{26,27,31-34} Nevertheless, the energy deficit and lactate production in the cells in response to a lack of oxygen can be limited and organ function can be improved by supplying pyruvate and pyruvate dehydrogenase activators, such as dichloroacetate.^{27,29,35-37} Intracellular acidosis may otherwise protect ischemic cells from dying.³⁶

The specificity of elevated lactate-to-pyruvate levels for an oxygen debt in the tissues has been doubted.^{27,38} Aerobic glycolysis is probably linked to the membrane Na⁺/K⁺-ATPase and stimulation of β_2 -receptors during sympathetic activation. Catecholamine (epinephrine) secretion may temporarily increase, rather than decrease, ATPase activity, and augment glycolysis and circulating lactate levels in tissues such as skeletal muscle, without a lack of oxygen and reduced ATP resources, during development and resuscitation from hypovolemic shock.^{38,39} Conversely, adrenergic antagonists may reduce lactic acidosis during hypovolemic shock.³⁸ Epinephrine may increase glycogenolysis. Together, increased glycolytic fluxes independent of oxygen uptake may lead to equal elevations of pyruvate and lactate in the tissues, without the acidosis resulting from ATP hydrolysis with an oxygen debt.²⁷ This situation may partly explain why the extent to which changes in the lactate level parallel changes in the anion gap or bicarbonate/base excess concentration during shock and resuscitation is controversial, and why elevated lactate levels sometimes may fail to predict an increase in oxygen uptake during an increase in oxygen delivery.⁴⁰⁻⁴² This also may explain in part the discrepancies in the course of oxygen-related variables and lactate levels during catecholamine treatment of shock when attempting to boost oxygen delivery.⁴²

The lactate level in blood is determined by production, distribution, and elimination.²⁷ Produced lactic acid in the presence of oxygen may be converted via pyruvate to glucose or oxidized. Bicarbonate is then released. The liver plays a central role in this process, so that the elimination of lactate and clearance from plasma is impaired in case of liver ischemia or prior hepatic disease, even though renal uptake may increase.^{27,43,44} Nevertheless, changes in the lactate level in blood, rather than absolute values, mainly reflect changes in production and are a fair measure for the course of shock and the response to therapy, even in the presence of liver disease.^{27,45} Although not beyond doubt, the origin of lactate in hypovolemic shock can be skeletal muscle, lung, and gut, particularly if severe liver ischemia, hypoxia, and acidosis in shock attenuate the hepatic uptake of lactate delivered by the gut through the portal vein.^{27,43,44,46-48} The respiratory muscles also may contribute to lactic acidosis in a spontaneously breathing patient because, first, the respiratory muscles may demand a share of the cardiac output at the cost of other tissues, and, second, this share may be insufficient to meet oxygen demands of the diaphragm, which may be increased in view of hyperventilation.^{33,49-52}

Notwithstanding the aforementioned limitations, an increase in the lactate level in blood and a decrease in the bicarbonate content/base excess or pH and an increase in the anion gap may be fair predictors of morbidity (multiple organ failure [MOF]) and mortality, whereas clearance of

*3, 6, 10, 11, 13, 16, 21-23

lactic acidosis usually indicates a better outcome. A decrease in the blood lactate level during resuscitation from hypovolemic shock is usually a favorable sign and associated with survival, whereas an increase in the lactate level and progressive acidosis usually are associated with morbidity and mortality, even though successful resuscitation may transiently increase the lactate level because of washout of lactate from ischemic tissues.* The mentioned variables may thus serve as guides for resuscitation.

OXYGEN BALANCE

Because insufficient uptake of oxygen relative to demand in the tissues during shock is central, insight into the factors that determine oxygen uptake in shock is important.^{25,27}

Oxygen delivery is determined by the cardiac output and the content of oxygen in arterial blood, that is, the arterial blood hemoglobin concentration and the saturation of hemoglobin with oxygen. The oxyhemoglobin dissociation curve determines the saturation of hemoglobin with oxygen for a given partial pressure of oxygen (P_{O_2}) in blood. During hypovolemic shock, a decrease in hemoglobin concentration, oxygen saturation, or both aggravates the effect of a decrease in cardiac output in compromising oxygen delivery to the tissues. Cardiac output is determined by preload, afterload, contractility, and heart rate.⁷

During a decrease in oxygen delivery with hypovolemic shock, the body maintains sufficient uptake of oxygen only if the extraction of oxygen increases, and the arteriovenous oxygen content gradient widens, resulting in a decrease in oxygen saturation of venous blood.[†] Associated with a decrease in oxygen delivery, tissue P_{O_2} declines, and its heterogeneity increases, possibly indicating focal ischemia.[‡] The decline in tissue P_{O_2} may be even greater than the decrease in draining venous blood because of some increase in microvascular oxygen shunting at low blood flows.^{68,69} In animals, it has been shown that the increase in oxygen extraction to compensate for a decrease in oxygen delivery is maximum (but not 100%) if oxygen delivery decreases to less than 8 to 15 mL/kg per minute, that is, the critical oxygen delivery (Fig. 26.1).[§] Although the critical oxygen delivery may vary widely among studies, following differences in species, basal oxygen needs, and methods to decrease oxygen delivery, data obtained in patients suggest that the critical oxygen delivery in humans may also amount to approximately 8 mL/kg per minute.^{58,64} During a decrease in oxygen delivery below this critical value in hypovolemic shock, oxygen uptake decreases to less than tissue demand, cellular ischemia ensues, and the body must rely on anaerobic metabolism to meet energy requirements.[¶] Blood lactic acidosis, lacticacidemia, results. Conversely, oxygen uptake is supply-dependent if oxygen delivery is lower than the critical value and blood lactate levels are elevated, whereas oxygen uptake may not be supply-dependent if the lactate level in blood is normal.^{||} Treatment of hypovolemic shock, by infusing fluids and blood, is aimed at an increase in

Figure 26.1 Relationship between oxygen uptake and oxygen delivery during progressive hypovolemia. Arrow indicates the critical oxygen delivery.

cardiac output and the oxygen content of blood and in oxygen delivery above the critical value so that oxygen uptake increases to meet body requirements and the lactic acidemia decreases.*

The critical oxygen delivery is a function of the body oxygen needs and the capability of the body to extract oxygen during a decline in delivery. The body oxygen needs may increase during hypovolemic shock, as a consequence of increased respiratory muscle activity and increased levels of catecholamines in the blood after activation of the sympathetic nervous system, but downregulation of the metabolic stimulant effect of catecholamines has been described.[†] The critical extraction of oxygen is a function of the adaptation of regional blood flow to tissue needs, the number of perfused capillaries and of diffusion distances, and the exchange surface area for oxygen.^{63,75} During a reduction in oxygen delivery, however, oxygen uptake is limited by convective transport of oxygen to the tissues, rather than by diffusion of oxygen to respiring mitochondria.⁷⁶

In experimental animals, a change in hemoglobin affinity for oxygen, by altering the storage duration of reinfused blood, hardly changes the critical oxygen extraction, but changes in acid-base status that affect the position of the oxyhemoglobin dissociation curve may have some effect on the oxygen extraction capabilities of the body.^{60,76} Acid infusion may increase slightly, and base infusion may reduce oxygen extraction during supply-limited oxygen uptake.⁷⁶ Nevertheless, hypercapnia may decrease critical oxygen extraction and increase critical oxygen delivery because of blood flow redistribution.⁷⁷ A leftward shift of the oxyhemoglobin dissociation curve may impair maximum oxygen extraction during a reduction in oxygen delivery and may increase mortality rate in experimental animals with hypovolemic shock.⁶⁰ Although the oxyhemoglobin dissociation curve may shift to the left in critically ill patients, for example, after transfusion of old, stored blood,⁷⁸ the effect on oxygen uptake is unclear.

The effect of changes in body temperature is twofold: Changes are accompanied by changes in total body oxygen needs and by changes in critical oxygen extraction, probably

by a vascular tone-associated altered distribution of blood flow.⁶¹ Hyperthermia increases critical oxygen delivery in hemorrhaged dogs, primarily through an increase in body oxygen needs and despite an increase in critical oxygen extraction, whereas hypothermia, which may be more common in traumatized or hemorrhaged patients, may decrease the critical oxygen delivery.⁶¹ Finally, blood viscosity may influence the extent to which a decrease in circulating blood volume affects oxygen uptake by the tissues. Experimental data suggest, however, that prior anemia does not ameliorate the decrease in oxygen uptake during a decrease in oxygen delivery with hypovolemic shock, indicating that the convective transport of oxygen is the major determinant of oxygen uptake when delivery is impaired, even though prior hemodilution may increase oxygen extraction capabilities and decrease critical oxygen delivery.^{6,70}

Taken together, these factors may influence the extent to which oxygen uptake decreases during reduced delivery and how far oxygen delivery should be enhanced during resuscitation from hypovolemic shock. The critical oxygen delivery varies among tissues. The oxygen needs of the kidney may decline during a decrease in renal oxygen delivery because a decrease in renal perfusion may lead to a reduction in glomerular filtration and to a reduction in energy-consuming tubular resorption.⁶³ In contrast, during progressive hypovolemia, the gut may experience supply dependency of oxygen uptake earlier than nongut tissue, partly because of a higher critical oxygen delivery (higher needs and less extraction of oxygen) and partly because of redistribution of blood flow away from the gut mucosa after more intense vasoconstriction in gut than in nongut tissue.* Clinically, this may result in nonocclusive bowel ischemia. Respiratory muscles may also have a higher critical oxygen delivery than the body as a whole during progressive hemorrhage.

Concomitant with an increased arteriovenous oxygen extraction during a decrease in oxygen delivery, the arteriovenous gradient of the carbon dioxide (CO₂) content widens.^{8,52,81} The latter is associated with an increase in tissue and venous partial pressure of carbon dioxide (Pco₂) relative to arterial Pco₂ and a decrease in venous pH exceeding the decrease in pH in arterial blood.^{44,52,68} This widening of gradient is caused by the Fick principle and a greater decline in cardiac output than in oxygen uptake and CO₂ production in the tissues because of inhibited oxidative metabolism. Nevertheless, the oxygen uptake usually decreases more than CO₂ production, leading to an increase in respiratory quotient.^{49,65} This increase is likely to be caused by buffering of lactic acid by bicarbonate in the tissues and effluent blood, a shift toward glucose instead of fat use for residual oxidation in ischemic tissues, or a combination of both. The end-tidal expiratory CO₂ fraction decreases in association with a reduction in oxygen uptake and CO₂ production for a given ventilation.⁶⁵ Conversely, a decrease in arterial Pco₂ during a decline in CO₂ production versus ventilation may be attenuated by an increase in dead-space ventilation resulting from a decrease in pulmonary blood flow/ventilation ratio.⁴⁹ An increase in deadspace

ventilation leads to widening of the gap between the arterial and expiratory Pco₂.⁴⁹

It has been suggested that the severity and duration of the oxygen debt accumulated during hypovolemic shock is a major determinant of survival in animals^{3,6} and in patients with trauma/hemorrhage and after major surgery.^{26,42,82} After trauma and hemorrhage, the defect in circulating blood volume and tissue oxygenation may be greater in patients who develop acute respiratory distress syndrome (ARDS) and MOF than in patients without these complications.* In patients undergoing major surgery, the oxygen debt during and after surgery may relate directly to the development of postoperative organ damage (i.e., MOF) and demise.^{73,82} Conversely, a high oxygen delivery and uptake during resuscitation may be associated with survival, whereas values that may be too low for elevated tissue demands are believed to contribute to ultimate demise, at least in animals with hypovolemic shock and critically ill patients after trauma or major surgery.[†] An increase of oxygen delivery and oxygen uptake to supranormal values has been suggested to improve survival further, although the latter debate has not been settled yet.[‡] Extensive ischemic mitochondrial damage may limit an increase in oxygen consumption during resuscitation and reperfusion.

MACROCIRCULATION

During loss of blood volume, various mechanisms come into play that may counteract the resultant decrease in cardiac output and tissue oxygenation. First, a decrease in cardiac output during hypovolemic shock results in a redistribution of peripheral blood flow.[§] This redistribution is partly the result of regional autoregulation to maintain blood flow, in which endothelial cells and production of endogenous partly gaseous vasodilators, including endothelial nitric oxide synthase-derived nitric oxide (NO), heme oxygenase-derived carbon monoxide, hydrogen sulfide, and metabolic by-products in the tissues including CO₂, potassium, and adenosine, may play a central role.⁸⁶⁻⁹⁴ Endothelium-derived NO relaxes underlying smooth muscle in the vessel wall, via stimulation of guanylate cyclase and cyclic guanosine monophosphate (cGMP), which can be inhibited by methylene blue.^{87,88,95,96} Carbon monoxide also acts via cGMP.⁹¹ Some authors describe that inhibition of endothelial NO synthase ameliorates early hypotension and even the mortality risk during bleeding.⁹² When NO is released, the reactivity to endogenous and exogenous vasoconstrictors may be diminished, even early in hypovolemic shock.^{92,97} Other authors describe endothelial injury and dysfunction in various organs with diminished endothelium and NO-dependent vasorelaxation, which could be overcome by L-arginine and other NO donors, including ATP-MgCl₂, pentoxifylline, or heparin, so that blockade of endothelial NO synthase-derived NO may be detrimental.^{87-89,97,98}

The opposing vasoconstricting factors include catecholamines, liberated by the activated sympathetic nervous system and the adrenal medulla; direct sympathetic stimulation of the vessel wall; angiotensin II, liberated through

§3, 63, 74, 79, 80, 85

an activated renin-angiotensin-aldosterone system; and vasopressin, released by the pituitary in hypovolemic shock.* Endothelin is an endothelium-derived potent vasoconstrictor, released on catecholamine stimulation or hypoxia, and its release may contribute to vasoconstriction, particularly in hepatic and renal vascular beds.^{100,101} Finally, a decrease in cardiac filling may reduce cardiac secretion of atrial natriuretic peptides, reducing the vasodilating and diuretic effect of these factors.¹⁰² Levels may also increase as a consequence of diminished renal clearance.^{103,104}

Depending on the degree that the mechanisms are operative, the general result of the interplay is that blood flow to intestines, skeletal muscle, and skin is diverted toward vitally more important organs, such as heart and brain, so that the increase of overall peripheral resistance during hypovolemic shock is distributed differently among various organs, with greater increases in gut, skeletal muscle, and skin than in heart and brain.[†] The kidney also is a target for hypovolemic shock; renal perfusion may be maintained during mild hypotension after hypovolemia, but it rapidly decreases if severe hypotension supervenes, and the decrease may exceed that in other organs.[‡] In hypovolemic human volunteers, this redistribution of blood flow accords with the patterns described.⁷⁴

The redistribution of blood flow results in a greater share of oxygen delivery going to organs with high metabolic demand, such as heart and brain, than tissues with less metabolic demands, including skin, skeletal muscle, kidney, gut, and pancreas.[§] The redistribution is probably necessary to optimize the uptake of delivered oxygen to the tissues and partly accounts for the increase in oxygen extraction during a decrease in oxygen delivery.^{63,75} In dogs, the ability of the body to extract oxygen diminishes with α -receptor blockade of sympathetic activity, suggesting that redistribution of blood flow aided by the sympathetic nervous system is a major determinant of critical oxygen extraction.⁶³

MICROCIRCULATION

Vasoconstriction after activation of the sympathetic nervous system during hypovolemia (hemorrhage) occurs in the arteries and medium-sized arterioles but not in terminal arterioles, which may even dilate, as judged from vital microscopy studies in animals.[¶] Relatively spared terminal arteriolar blood flow is presumably caused by vasodilating metabolic responses to a decline in nutrient blood flow. Nevertheless, capillary flow usually diminishes, and heterogeneity, both in space and time, increases, particularly in irreversible shock and independent of cardiac output.^{||} Traumatic/hypovolemic shock may induce expression of adhesion molecules on primed neutrophils and vascular endothelium and this, together with a reduced flow rate, may promote adherence of neutrophils to endothelium.^{95,111-119} This adherence may impair red blood cell flow, particularly in capillaries and postcapillary venules.^{||}

Other authors suggest that capillary leukostasis is pressure-dependent and not receptor-dependent and reversible when perfusion pressure has been restored.¹²¹ Finally, endothelial cells may swell and may hamper capillary red and white blood cell flow.^{95,98,110,122} The microcirculation can be visualized, even in humans, by buccal or sublingual orthogonal polarization spectroscopy and side stream dark-field imaging.¹²³

Vasoconstriction is not confined to arteries, but also occurs in the venous vasculature, more in large than in small venules and particularly in the splanchnic area, and, again, this is largely mediated by increased activity of the sympathetic nervous system and vasopressin and angiotensin II release.^{5,12,68,108} Because most of the circulating blood volume is located in small venules, splanchnic venoconstriction results in a decrease in compliance and less volume for a given intravascular pressure in the venous system, increasing return of blood to the heart.^{5,7} Hence, partitioning circulating volume in stressed and unstressed portions now favors the former. During hypovolemic shock, the precapillary to postcapillary resistance increases, resulting in a decrease in capillary hydrostatic pressure and in fluid resorption from the interstitial space as opposed to normal filtration from capillary to interstitium, even though interstitial hydrostatic pressure decreases.^{4,5} This is accompanied by diminished transport of protein from blood to interstitium.¹²⁴

Cellular water is mobilized, unless, at a later stage, the cell swells following Na^+ overload.^{21,98,110,125-129} Studies on fluid volumes in hypovolemic shock are not equivocal, but generally suggest that the interstitial and cellular compartments are depleted in defense of the circulating blood volume to promote venous return to the heart.^{5,7,125,126} Mobilization of fluid from the interstitial and cellular compartment can be promoted by plasma hyperosmolarity, through an increase in the glucose concentration.^{130,131} Chronically starved rats with depleted glycogen stores more rapidly die of hypovolemic shock than fed ones, and this can be prevented by prior glucose infusion.¹³⁰ In addition, the lymphatics may show increased pumping ability, increasing return of fluid into the systemic circulation independently of the reduced capillary fluid filtration rate.¹³² Lymphatic return of interstitial protein and fluid may contribute to repletion of circulating protein and fluid volume.¹³²

Hemorrhage and hypovolemic shock lead to a decrease in hematocrit and a decrease in plasma proteins through transfer of fluid (and protein) from the interstitial to the intravascular space.^{4,5,124} Refilling of the intravascular space diminishes in time after a sudden decrease in circulating volume, when a decline in colloid osmotic pressure, associated with hypoproteinemia, and an increase in hydrostatic pressure accomplish a new steady state in capillary exchange through readjustment of the pericapillary hydrostatic and colloid osmotic pressures, which determine fluid and protein transport.⁵ Conversely, hypoproteinemia can promote transcapillary fluid transport and expansion of the interstitial space, if hydrostatic pressure returns toward normal (e.g., during crystalloid fluid resuscitation).^{126,133-136} During a sudden decrease in circulating blood volume by hemorrhage, some time is needed before the decrease in hematocrit and of proteins in blood is completed, and this decrease is aggravated by nonsanguineous fluid

resuscitation.^{126,134,137} Finally, increased sympathetic discharge results in contraction of the spleen, releasing red blood cells into the circulation and defending a fall in hematocrit.¹⁴

CELLS

During hypovolemic shock, the oxygen lack in the tissues causes a decline in the mitochondrial production and concentration of high-energy phosphates in the tissues because of greater breakdown than production of these compounds.^{24,29,46,138,139} This decline is a function of the severity and duration of regional hypoperfusion relative to oxygen demand. The decrease in the redox status and high-energy phosphates during experimental hypovolemic shock is more pronounced in some tissues (diaphragm, liver, kidney, and gut) than in others (heart and skeletal muscle), so regional lactate production may vary.*

A decrease in high-energy phosphates heralds irreversible cell injury during ischemia, whereas a less severe decline may result only in prolonged programmed cell death—apoptosis. In animals with hypovolemic shock and in critically ill patients, the circulating levels of ATP can be diminished, and ATP degradation products, including adenosine, inosine, hypoxanthine, and xanthine, can be elevated, suggesting breakdown of ATP following a lack of oxygen in the tissues.^{28,29,56,141,142} Conversely, reperfusion is associated with restoration of energy charge, depending on the effect of ischemia, the oxygen demand, and the level of reperfusion. The intravenous administration of energy in the form of ATP-MgCl₂ may help tissues (kidney, liver, heart, gut) to recover from ischemia and resume function, independently of the vasodilating effects of the compound.^{24,128,143,144} Also, pretreatment with coenzyme Q₁₀, involved in the respiratory chain reactions in mitochondria, has a beneficial effect during hypovolemic shock and resuscitation, at least in dogs.⁸¹ Nevertheless, part of the mitochondrial dysfunction after trauma and hypovolemic shock has been suggested to be independent of a lack of oxygen.⁵³ Near-infrared spectroscopy, which can be applied in animals and patients, may indeed reveal normal absorption spectra for tissue oxyhemoglobin and low mitochondrial cytochrome *aa3* redox status.^{53,123,145}

About 60% of the energy produced by respiring mitochondria is needed to fuel the Na⁺/K⁺ pump of the cell, through which the gradient in electrolyte concentrations and electrical potential over the cell membrane are controlled.²⁴ When ATP becomes insufficient because of a decline in production associated with lack of oxygen and production of protons increases, the Na⁺/K⁺ pump is inhibited and the Na⁺/H⁺ exchanger is activated, and this results, together with a possibly selective increase in cell membrane permeability for ions, in an influx of Na⁺ into and efflux of H⁺ and K⁺ out of the cell, leading to cellular uptake of fluid.[†] Measurement of membrane potentials of skeletal muscle and liver in experimental animals has shown that hypovolemic shock rapidly decreases the transmembrane potential (a less negative inner membrane potential), associated with electrolyte and fluid shifts across the cell membrane.[‡] A

decrease in activity of the Na⁺/K⁺ pump may contribute to hyperkalemia because of potassium exchange between cells, interstitial fluid, and vascular space.^{38,46,111,125} Finally, calcium (Ca²⁺) influx into cells and their mitochondria inhibits cellular respiration and ultimately contributes to cellular damage and swelling, particularly during resuscitation, and this can be prevented by administration of Ca²⁺ antagonists.* Because of cellular influx, the plasma-free Ca²⁺ levels may decrease in experimental and human hypovolemic shock.^{127,149,150} Intracellular lysosomes lose their integrity so that proteolytic enzymes are released and contribute to cell death.^{4,24,107,151} These enzymes eventually may reach the systemic circulation and may damage remote organs.^{4,24,107,151}

As has become apparent in past years, the cellular response to stress, such as heat and tissue hypoxia, involves the expression of certain genes, coding for synthesis of the so-called heat-shock proteins, which play an important role in protecting the cells against stress.¹⁵²⁻¹⁵⁵ The clinical significance of these molecular cellular changes is unknown. The response may be partially responsible, however, for the decreased susceptibility to and tissue injury by hemorrhagic shock in animals with a prior challenge by endotoxin or other forms of preconditioning.^{113,156}

ORGAN PERFUSION AND FUNCTION IN SHOCK

HEART

According to Starling's law of the heart, a change in preload, approximated by the end-diastolic volume and determined by the venous return of blood to the heart, directly results in a change in stroke volume, defining myocardial function.⁷ The relationship between end-diastolic filling pressure and volume reflects compliance. Apart from preload, cardiac output also depends on afterload, which is approximated by the end-systolic volume of the heart, and contractility, reflected by the peak systolic pressure-to-volume relationship (maximal elastance).^{7,55,157} A diminished response of the stroke work by the heart, that is, the product of stroke volume and arterial blood pressure, to an increase in preload during resuscitation from hypovolemic shock may indicate diminished cardiac contractility that is associated with a worse outcome (e.g., caused by preexisting cardiac disease, hypovolemic shock itself, myocardial contusion, or combinations).^{4,55,158,159} The effect of hypovolemic shock on myocardial function in animal models is controversial. Depending on models, methods, and definitions of cardiac dysfunction, some authors describe a decrease, but others describe an unchanged function of the left side of the heart.[†] The latter can be explained if a decrease in contractility of the heart is masked by the inotropic effect of catecholamines and other positive inotropic substances, such as endothelin, liberated during hypovolemic shock, even though receptor-mediated catecholamine responses may decline.^{4,23,100,160}

Although coronary blood flow may be defended, and the oxygen demands of the heart may decrease associated with a decrease in filling (preload) and arterial blood pressure (afterload) during initial hypovolemic shock, hypotension

*24, 38, 46, 106, 139, 140

†24, 46, 111, 125, 127, 146, 147

‡24, 46, 111, 125, 127, 146

*24, 125, 127, 139, 148, 149

†4, 127, 157, 158, 160, 161

may become so severe that coronary vasodilation to compensate for a decline in perfusion pressure becomes exhausted, so that myocardial oxygen delivery decreases to less than the oxygen needs of the heart and ischemia ensues, particularly if tachycardia is present.^{3,21,140,161-163} This sequence leading to ischemia may occur primarily in endocardium because of more rapidly exhausted vasodilation in endocardium than epicardium and redistribution of blood flow from the inner to the outer layer of the heart.¹⁴⁰ The sub-endocardium may become ischemic, and patchy necrosis may ensue. Because of regional transmural and intramural differences in vasodilator reserve, myocardial ischemia may be heterogeneously distributed and associated with a diminished redox state, lactate production, and creatine phosphate breakdown.^{140,164} Ischemia ultimately may contribute to a decrease in myocardial contractility during hypovolemic shock. Smooth muscle-dependent and, particularly, endothelium-dependent coronary vasomotion may be impaired after hypovolemic shock.^{89,165} Myocardial edema and compression of capillaries with resultant impairment of diffusion and extraction of oxygen may also contribute to a decrease in regional coronary blood flow, regional myocardial ischemia, and decreased myocardial function in hemorrhaged animals.^{127,131,140,161}

Hypovolemic shock may induce a decrease in left ventricular compliance and relaxation.^{160,161} The diastolic dysfunction may be particularly pronounced during resuscitation from hypovolemic shock.^{157,160,161} Postischemic failure (stunning) also may play a role during resuscitation, at least temporarily. Ischemia-reperfusion of the heart results in accumulation of intracellular Ca^{2+} .¹²⁷ This may impair mitochondrial and sarcoplasmic reticulum function and contribute to impaired cardiac function after hypovolemic shock.^{127,160} In dogs, the administration of Ca^{2+} blockers may prevent such deterioration during resuscitation from hypovolemic shock.¹²⁷ Finally, systemic release or intramyocardial production of negative inotropic substances and inflammatory mediators such as tumor necrosis factor (TNF)- α , interleukin (IL) 6 and platelet activating factor, oxidant damage, metabolic acidosis, diminished adrenoceptor density, and resultant diminished sensitivity of the heart to circulating catecholamines may contribute to myocardial dysfunction during hypovolemic shock.* Pentoxifylline may improve endothelial and myocardial function.¹⁶⁶ Reversibility of dysfunction is associated with survival.¹⁶¹

The clinical evidence for myocardial dysfunction during hypovolemic shock is scarce.^{46,55,163} Nevertheless, it is conceivable that severe hypotension reduces the balance between oxygen delivery and demand of the heart because many patients with hypovolemic shock may be elderly with coronary artery disease, compromising coronary vasodilation. Some may have preexisting impaired function while on beta blockers. For a patient with hypovolemic shock, a decrease in left ventricular compliance, contractility, or both may imply that a relatively high filling pressure would be needed to restore cardiac output during fluid resuscitation.^{55,71,161,163,171} The averaged optimal pulmonary capillary wedge pressure (PCWP), that is, the pressure above which

cardiac output does not increase further, may not be elevated in patients with hypovolemic shock (i.e., 12 to 15 mm Hg), although in some patients, abnormally elevated filling pressures may be needed to increase cardiac output, or cardiac output does not increase at all during fluid resuscitation.^{55,71,171,172} A diminished function of the heart may hamper restoration of oxygen delivery to the tissues during resuscitation necessary for survival.^{9,45,55,159,160} Myocardial dysfunction may thus be greater in nonsurvivors than in survivors. There may be some electrocardiographic or enzymatic evidence for myocardial ischemia and injury, and some patients may experience a myocardial infarction as a complication of severe hypovolemic shock after hemorrhage.^{163,173}

LUNG

Hypovolemic shock often induces an increase in ventilatory minute volume, resulting in tachypnea or hyperventilation and a decrease in arterial PCO_2 .^{33,49,50,52,174} Unless complicated by pulmonary abnormalities, these changes are, at least initially, not the result of hypoxemia but an increase in dead-space ventilation following a decrease in pulmonary perfusion so that a higher minute ventilation is necessary for a given CO_2 production to eliminate CO_2 from the blood and to maintain a normal PCO_2 in arterial blood.^{33,49,50} Minute ventilatory volume may increase further if a decrease in PCO_2 is necessary to compensate for metabolic acidosis after accumulation of lactate in the blood.* The imbalance between increased demands of the diaphragm and reduced blood flow in shock may finally lead to respiratory muscle fatigue and a subsequent decline in ventilatory minute volume.⁵⁰

Hypovolemic shock caused by trauma and hemorrhage and followed by extensive transfusion therapy of red blood cell concentrates can be complicated by pulmonary edema and impaired gas exchange.^{51,175-180} In some patients, fluid overloading, overtransfusion, and an elevated filtration pressure (PCWP) may be responsible: transfusion-associated circulatory overload (TACO). In others, pulmonary edema may be due to a pulmonary vascular injury, however, and increased vascular permeability at a relatively low PCWP, indicating noncardiogenic permeability edema or ARDS.^{51,174,177,178} The reaction to diuretics may help to differentiate between hydrostatic and permeability edema of the lungs. The latter seems relatively rare in polytransfused, polytraumatized patients unless associated with complications, but other studies suggest that about 30% of patients with severe trauma/hemorrhage, particularly if polytransfused, may develop ARDS.^{177,178,180,181}

Experimental studies are at variance concerning alterations in capillary permeability of the lungs during hypovolemic shock and resuscitation.^{4,133,174,182,183} According to some investigators, hypovolemic shock following bleeding and transfusion mildly increases transvascular filtration of fluid and proteins and results in accumulation of interstitial fluid as a consequence of increased permeability,¹⁸² but other authors do not observe such changes.^{131,133,182,184} In other animal studies, however, traumatic/hypovolemic shock resulted in extensive morphologic changes of the lung,

with endothelial and interstitial edema, accumulation of degranulated neutrophils, and scattered fat emboli, which may resemble the pulmonary changes after traumatic/hypovolemic shock in humans.^{156,174,185-187} As measured by the transvascular albumin flux in the lungs, almost 80% of patients with multiple trauma may show increased pulmonary vascular permeability in the disease course.⁵¹ This leak ultimately may contribute to pulmonary edema, impaired mechanics, and gas exchange.⁵¹ As suggested by animal experiments, among others, several factors may play a role, including release of proinflammatory mediators (TNF- α) and priming and activation of blood neutrophils after ischemia-reperfusion, contusion or ischemia-reperfusion of the lungs themselves, pulmonary microemboli of neutrophils, platelets and fat particles from the medulla of fractured long bones and pelvis, and neutrophilic antibodies or humoral or cellular breakdown products and released cytokines in long-stored and transfused blood products (transfusion-related acute lung injury, TRALI).^{*} Translocated endotoxin may also play a role.¹⁸⁵ Finally, aspiration of foreign material or gastric contents and posttraumatic pneumonia and sepsis may contribute to the development of ARDS in trauma patients. When pulmonary edema has developed, active resorption by alveolar cells becomes necessary for clearance. This process is cyclic AMP-dependent and can be disturbed by inducible nitric oxide synthase (iNOS)-derived NO and peroxynitrite and enhanced by expression of heme oxygenase, which may mitigate lung injury in animal models.¹⁵⁶ How this translates clinically is unclear.

BRAIN

Classically, brain perfusion and microcirculation are considered to be relatively spared during progressive hypovolemia because of the extensive autoregulatory capacity of cerebral arteries.^{15,189} In case of autoregulation impairment after neurotrauma, however, brain perfusion may decrease, and subsequent reperfusion may contribute to secondary cerebral damage during hypovolemic shock and resuscitation. Hemorrhagic shock and resuscitation per se may also impair autoregulatory capacity of brain vessels, however, because of endothelial dysfunction and diminished NO-dependent vasodilator reactivity, so that the brain may experience an oxygen debt and subsequent metabolic and functional deterioration.^{29,88}

KIDNEY

Hypovolemic hypotension is an important risk factor for acute kidney injury and failure after trauma.¹³⁸ During a decrease in cardiac output following progressive hemorrhage, renal blood flow can be maintained because of renal vasodilation, so that the kidneys may not participate in the systemic vasoconstriction that characterizes hypovolemic shock.³ Vasodilating prostaglandins are released in the kidney through activation of the cyclooxygenase pathway of arachidonic acid metabolism in response to ischemia, increased sympathetic activity, and angiotensin II, so that renal vasodilation during the early phase of hemorrhage can be blocked by prostaglandin synthesis inhibition,

resulting in a profound decrease in blood flow even if accompanied by an increase in arterial blood pressure.³ When blood pressure decreases during progressive hypovolemia, the renal vessels constrict, impairing blood flow to the kidneys more than to other organs.^{*} This is partly caused by a baroreflex-mediated increase in sympathetic activity; activation of the renin-angiotensin-aldosterone system; and release of catecholamines, angiotensin II, endothelin, and vasopressin.^{13,14,74} During prolonged hypovolemic shock, sympathetic inhibition may protect against renal ischemia.¹⁴ This propensity for vasoconstriction is thus partly offset if NO and other factors with vasodilatory actions are released intrarenally.^{4,86} Inhibition of NO synthesis increases blood pressure, however, and increases renal perfusion and glomerular filtration during hypovolemic shock.⁸⁶ In another study, endothelium-dependent renal vasodilation was impaired after hypovolemic shock.⁸⁷

Renal ischemia results in a decrease in glomerular filtration (prerenal renal failure) that is less than the decline in blood flow so that the filtration fraction often increases.¹³⁸ The latter is caused by greater constriction of efferent than of afferent arterioles in glomeruli, in which high levels of circulating angiotensin II are probably involved. The decrease in glomerular filtration together with an increase in tubular resorption of electrolytes and fluids, mediated by increased levels of antidiuretic hormone released by the pituitary and decreased levels of atrial natriuretic peptides through low atrial filling, results in oliguria or anuria (<0.3 mL/kg/hour) and a low sodium content of urine.¹³⁸

The decrease in renal perfusion during hypovolemic shock is often accompanied by redistribution of blood flow from outer to inner cortex and medulla, which is already borderline hypoxic even in the normal state.¹²⁷ If long-lasting and severe, the cortical kidney becomes ischemic, despite a decrease in oxygen needs associated with fewer energy needs for tubular resorption in the presence of less filtration, so that the levels of high-energy phosphates decline.^{138,139} Severe and prolonged renal ischemia and metabolic deterioration finally result in acute kidney injury and failure with morphologic changes, particularly in proximal tubules and medullary segments (acute tubular necrosis) when an increase in renal perfusion does not immediately restore filtration and diuresis, but rather injures renal structures (reperfusion injury), limiting a return of blood flow and glomerular filtration during resuscitation.^{129,138,185,186} This is often recognized by a persistent oliguria and a gradual increase in creatinine and urea levels in blood. In addition, the plasma levels and urinary excretion of biomarkers of injury and dysfunction may increase.¹⁰⁴

GUT

During hypovolemic shock, blood flow from stomach to colon is redistributed to other organs, and this may be primarily mediated by elevated sympathetic activity and increased levels of vasopressin and angiotensin II even though vascular reactivity to the latter may diminish.[†] Vasoconstriction may overwhelm NO and other vasodilating mechanisms, and endothelium-dependent vasodilation may

*51, 117, 174, 175, 180, 183, 185, 187-191

*3, 14, 74, 85, 86, 106, 139

†3, 13, 14, 22, 79, 80, 97, 105, 139, 152, 192, 193

be impaired after oxidant endothelial injury.¹⁹⁴ Gut ischemia is aggravated further by the countercurrent mechanism in mucosal (villous) blood flow, promoting diffusional shunting of oxygen from arteries to veins, bypassing tissues. Other studies reported that gut mucosal blood flow may be relatively spared during hypovolemia, however.^{75,105} Portal blood flow decreases, and portal blood levels of lactate increase after gut ischemia.^{27,48,195}

Gastric mucosal ischemia may result in diminished energy-consuming acid production and may predispose to mucosal stress ulceration.^{192,196} Microscopic studies in experimental animals show damage of gastric mucosa, villous epithelium in small bowel, and mucosa of the large bowel after hypovolemic shock.^{114,192,197-199} Gastric mucosal ischemia-reperfusion injury after bleeding may be aggravated by gastric acid itself, neutrophils, inflammatory mediators, endothelin, reactive oxygen species (ROS), and proteases.^{198,200} Bowel ischemia and mucosal damage during hypovolemic shock in the dog may ultimately lead to leakage of fluid from the bloodstream to the bowel lumen, instead of normal resorption of luminal fluids.^{115,197} Diarrhea may contribute to intravascular volume depletion during severe and prolonged hypovolemic shock, at least in animals.

Gut mucosal ischemia, energy depletion, injury, and inflammation may compromise the barrier function of the mucosa, enhancing the likelihood that bacteria and endotoxins in intestinal lumen (large bowel) translocate through the damaged gut wall to lymph nodes, portal venous blood, or both.* The gut epithelial (lumen to plasma) permeability for small molecules also is increased. Indigenous flora, generated toxic ROS, cytokines, Ca²⁺ overload, iNOS, peroxynitrite, phospholipase A₂ activation, and activated and adhering neutrophils during ischemia and reperfusion probably all play a role in the injury, promoting hyperpermeability and translocation.^{199,203} Mucosal injury and translocation can be inhibited by compounds targeted against these factors.¹⁹⁹ Impaired detoxifying capacity of the Kupffer cells of the liver because of ischemia or preexistent liver disease may contribute further to bacteria and endotoxins reaching the systemic circulation and contributing to progression of shock by triggering an inflammation cascade, ultimately resulting in release of vasoactive substances.^{4,204,205} This translocation has been shown to contribute to the lethality of hypovolemic shock in experimental animals because clearance or blockade of translocated bacteria and endotoxins is associated with survival, and germ-free animals survive an episode of bleeding more often and longer than ones with normal intestinal flora.^{4,143,203,205} Finally, it has been shown that the absorptive capacity of the gut for carbohydrates, amino acids, and lipids decreases during hypovolemic shock.^{148,195} Although enteral feeding during hypovolemic shock and after resuscitation may increase metabolic demands of the gut, there is experimental evidence that luminal application of nutrients, particularly of enterocyte-fueling glutamine, induces an increase in small vessel blood flow, ameliorates damage, and diminishes the likelihood for translocation of endotoxins and bacteria during resuscitation from hemorrhage.²⁰⁶

In humans, hypovolemia leads to a decline in hepatosplanchnic perfusion.⁷⁴ Stomach mucosal lesions may be

common after prolonged hypovolemic shock, but overt bleeding is a relatively rare event, particularly in a rapidly, adequately resuscitated patient.²⁰⁷ Agents that decrease energy-demanding gastric acid production may protect against stress ulcers during mucosal ischemia.¹⁹⁶ The gut is usually quiescent during hypovolemic shock in humans. Ileus is often present, and the patient is managed expectantly until bowel sounds return and enteral feeding is likely to be tolerated. Occasionally, a bowel infarction and perforation may complicate hypovolemic shock as a consequence of nonocclusive ischemia.¹⁴⁸ Gut absorptive capacity may decrease,¹⁴⁸ perhaps caused by gut ischemia. The adequacy of gastrointestinal blood flow can be monitored in humans with the help of a balloon catheter in the stomach (or gut), in which fluid or air is installed, or sublingually or buccally with help of a sensor (tonometry).* The mucosal PCO₂ thus measured decreases, and the mucosal-to-blood PCO₂ gradient increases, during a decrease in mucosal blood flow relative to demand. An increase of this gradient may occur at an earlier stage than an increase in heart rate or decrease in arterial blood pressure during progressive hypovolemia, constituting an early and sensitive sign of shock.²⁰⁸ Gastrointestinal tonometry can be used as a guide for resuscitation.† The clinical occurrence and significance of translocation of intestinal bacteria and endotoxins to mesenteric lymph nodes and the bloodstream are unclear, although the capacity of the human gut wall to resorb orally administered small molecules, including lactulose relative to mannitol, may increase, indicating epithelial barrier dysfunction.^{54,204,205,211-214}

LIVER

Liver microvascular and sinusoidal perfusion decline during hypovolemic shock because of diminished portal and hepatic arterial blood flow, roughly in proportion to the decrease in cardiac output so that in contrast to the gut there is no angiotensin II-mediated selective vasoconstriction in the hepatic arterial bed.‡ Endogenous mechanisms, including release of NO, carbon monoxide, and hydrogen sulfide in the absence of endothelial dysfunction, may counteract a decrease in perfusion, which is promoted by thromboxane A₂ and endothelin.^{91,155} A decrease in blood flow may result in liver ischemia, a decrease in high-energy phosphate contents and clearance function as evidenced by insufficient capacity to clear indocyanine green from blood and a decrease in the bile excretion rate.§ The capacity to clear gut-derived endotoxin, cytokines and lactate also may decrease, and the ischemic liver produces lactate.⁴³ Hepatic ischemia may result in a diminished capacity for metabolism of drugs such as lignocaine²¹⁹ and for gluconeogenesis from lactate and amino acids, contributing to hypoglycemia in the late stage of hypovolemic shock.^{12,139} Inflammation of the liver causes cytokine expression; hepatic sinuses become filled with adherent neutrophilic aggregates, lining cells may swell, and microcirculatory failure and centrilobular necrosis/apoptosis may ensue with leakage of enzymes

into the circulation.* ROS and NO-derived and toxic peroxynitrite and damage of endoplasmic reticulum and mitochondria may be involved. Clinically, bilirubin and transaminases may be transiently elevated in blood, abnormalities attributed to ischemic hepatitis.^{222,223} A clinically useful measure of hepatic oxygen debt is an increase in the plasma ratio of β -hydroxybutyrate to acetoacetate (ketone body ratio), which occurs concurrently with a decrease in the hepatic mitochondrial redox state.^{28,91,95,223}

SPLEEN

The spleen contracts during hypovolemic shock, probably caused by increased sympathetic activity, and this results in release of red blood cells into the circulation.^{3,14} Changes in hematocrit during the early phase of bleeding probably underestimate the severity of plasma losses. The spleen also releases stored platelets.

PANCREAS

The pancreas is severely ischemic during hypovolemic shock.¹⁰⁷ Ischemic pancreatitis may lead to autodigestion of acinar cells and liberation of pancreatic lysosomal enzymes into the systemic circulation, including proteases and factors with negative inotropic properties on the heart, although the latter factors may also come from ischemic gut.^{4,107,166} Ligation of the pancreatic duct may be beneficial in experiments by preventing gut injury and barrier failure, among others.²²⁴

HORMONES AND METABOLISM

As mentioned before, a severe decrease in cardiac output resulting in a decrease in arterial blood pressure during hypovolemic shock results in activation of the sympathetic nervous system through the baroreceptor reflex and liberation of norepinephrine from nerve endings and epinephrine from adrenal medulla so that circulating levels of these catecholamines increase.^{11-13,74,81,99} The insulin secretion by the pancreas is inhibited, and glucagon secretion is enhanced by high circulating norepinephrine levels.⁹⁹ The renin-angiotensin-aldosterone system is activated, and the pituitary secretion of vasopressin/antidiuretic hormone and opioids increases.^{11-13,23,99} The pituitary response to stress further includes an increase in adrenocorticotrophic hormone (ACTH) with resultant corticosteroid release by the adrenal cortex, unless limited by the so-called relative adrenal insufficiency following hypoperfusion-induced adrenal damage.^{12,99,152} These factors may be essential for survival because prior adrenalectomy decreases survival of animals subjected to hypovolemic shock, and steroid repletion is protective in this respect.¹² This protective effect can be attributed to, among others, less overactivation of the sympathetic nervous system and increased sensitivity of the heart and vasculature to circulating levels of catecholamines.¹²

Finally, the secretion of atrial natriuretic peptides by the myocardium declines in response to hypovolemia and diminished wall stress of the atria. These factors, among others, result in tachycardia and a diminished renal

excretion of water and salt to restore circulating blood volume. Endogenous opioids could play a role in maintaining shock by their vasodilating and myocardial depressant properties, however.^{11,13,23} Administration of the opioid antagonist naloxone and its derivatives augment arterial blood pressure in hypovolemic shock.^{13,23,143,225} Similarly, thyrotropin-releasing hormone depresses the opioid system and increases arterial blood pressure, cardiac function, and survival during hypovolemic shock in animals.²³ Thyroid hormone may have a similar effect.²²⁶

During trauma, hypovolemic shock, and cellular ischemia, intermediary metabolism undergoes profound changes, partly caused by an altered hormonal milieu.⁹⁹ The early hyperglycemic response to traumatic/hypovolemic shock is the combined result of enhanced glycogenolysis, caused by the hormonal response to stress and elevated epinephrine, cortisol, and glucagon levels; increased gluconeogenesis in the liver, partly mediated by glucagon; and peripheral resistance to the action of insulin, the secretion of which may be diminished shortly after onset of shock but may be enhanced later after shock.^{24,47,99,129} This resistance is most likely the result of an altered hormonal milieu—the increase in circulating epinephrine and cortisol levels. During the late, irreversible stage of hypovolemic shock, however, hypoglycemia supervenes, at least in animal models, because glycogen stores may be depleted and the capacity for gluconeogenesis by the liver may decrease because of ischemia.^{12,24,47,111,130}

Increased gluconeogenesis in the liver, and to a lesser extent in the kidneys, follows increased efflux of amino acids such as alanine and glutamine from the muscle to the liver because of breakdown of muscle protein.^{99,222} The latter is evidenced by increased urinary losses of nitrogen and a negative nitrogen balance.^{99,222} Amino acid metabolic changes may contribute to the immunodepression of trauma. Lactate produced in muscle also can be converted to glucose in the liver.⁹⁹ Finally, fatty acid metabolism undergoes profound changes, with depressed lipolysis, ketogenesis, and combustion of fatty acids during shock and an increase in the resuscitation phase.^{99,222} Some investigators regard a deranged intermediary metabolism of primary importance for the eventual outcome of shock, whereas others merely consider these changes a result of the shock process itself.²²²

INFLAMMATORY AND IMMUNOLOGIC CHANGES

Activation of the xanthine-oxidase system and formation of uric acid from the ATP breakdown products hypoxanthine and xanthine during reperfusion could liberate ROS, which damage vascular endothelium and parenchymal cell membranes through peroxidation of lipids.* The release of ROS during ischemia-reperfusion may activate macrophages and attract neutrophils, partly mediated by release of cytokines via activated nuclear factor- κ B (NF- κ B).^{194,228} The interaction of ROS fueled by oxygen and NO may further play a role in inflammation and vascular tone after perfusion.^{90,228} ROS scavengers may inhibit formation of toxic

*95, 166, 185, 186, 216, 220, 221

*117, 188, 198, 199, 227, 228

peroxynitrite via NO, and ROS and may inhibit breakage of DNA single strands and activation of poly(ADP-ribose) polymerase, which contributes to cellular injury.^{90,92,221} Some time after hypovolemic shock and resuscitation, iNOS may become active particularly in the gut and liver; circulating NO breakdown products may increase and inhibition of the excessive NO release may ameliorate hemodynamic changes, organ inflammation, and neutrophil accumulation and function, partly via less peroxynitrite formation, unless inhibition leads to a decrease in cardiac output.^{90,92,155,220} Increased iNOS-derived NO also may be prevented and treated by corticosteroids or ACTH fragments.^{93,229}

Proinflammatory mediators may be expressed locally in a variety of organs in response to hemorrhagic shock, including heart and lungs, and this is partly under control of α -sympathoadrenergic and neuroimmune stimuli, toll-like receptor 4, NF- κ B, hypoxia-inducible factor, glycogen synthase kinase-3 β , and other factors involved in cell signaling.^{228,230-233} During and after hemorrhage, hypovolemic shock, and resuscitation, macrophages, including lung macrophages and Kupffer cells in the liver, may release cytokines, including TNF- α , IL-1, IL-6, and IL-8. This inflammatory response is attenuated when reperfusion takes place in hypoxic, rather than normoxic, conditions.²³⁴ The response can be ameliorated by blockade of NF- κ B, administration of the macrophage-inhibitor pentoxifylline, or ATP-MgCl₂ increasing hepatic blood flow.*

Ischemia per se and the immune consequences of gut barrier injury may play a role in Kupffer cell responses. The reperfused gut, together with the liver, may be a source of systemically released cytokines, as suggested by animal experiments and observations in humans after trauma, and translocated endotoxin may play a role.[†] During reperfusion after resuscitation, cytokines may induce and amplify the inflammatory response to ischemia and may induce further local and remote organ damage with circulatory changes.^{166,187,236,240,241} Spillover of mediators into the mesenteric lymph or portal and systemic circulations during reperfusion of prior ischemic gut may have deleterious effects on remote organs by inducing neutrophil activation and adherence, which may contribute to a lung vascular injury with increased permeability.^{185,186,188,240,241} Circulating levels of proinflammatory cytokines may be of predictive value for remote organ damage, including ARDS, after trauma in patients.^{230,237,238} Endotoxin binding or antibodies and cytokine antibodies may ameliorate remote tissue damage after bleeding, hypovolemic shock, and resuscitation.^{185,186}

Trauma and shock/resuscitation have also been shown to activate the complement and the arachidonic acid systems.^{151,242-245} Complement activation may yield potent vasodilating and leukoattractant substances and contribute to remote inflammatory organ damage (ARDS). Ischemia may generate phospholipase A₂, catalyzing arachidonic acid metabolism into prostaglandins via the cyclooxygenase pathway, releasing thromboxane A₂ and prostacyclin, and into leukotrienes via the lipoxygenase pathway.^{10,151,243} Thromboxane A₂, released from platelets, neutrophils, and cell membranes, has potent vasoconstricting properties

and promotes aggregation of platelets and neutrophils, whereas prostacyclin has vasodilating properties and inhibits platelet and neutrophil aggregation.²⁴³ Leukotrienes have vasoconstricting properties, increase capillary permeability, and attract neutrophils.¹⁵¹ Vasoconstricting prostaglandins may be involved in tissue damage during ischemia-reperfusion, and vasodilating prostaglandins may be involved in the vasodilated state of terminal hypovolemic shock.^{10,242} Another lipid mediator that may be released is platelet-activating factor, but the precise action of this mediator is unclear.^{149,170}

The interplay of these factors may result in endothelial activation throughout the body and an inflammatory reaction, ultimately involving attraction, activation, and endothelial adherence of neutrophils, as shown in animal models of hypovolemic shock after bleeding and ischemia-reperfusion.* Neutrophils release vasoconstricting, platelet-aggregating, and damaging thromboxane A₂ and may inhibit vasodilating prostacyclin, via secreted ROS and proteases such as elastase.^{117,228,238,244,246} Neutrophil aggregation and secreted activation products also may play a role in the reperfusion injury by impairing resumption of small vessel blood flow, even in the presence of a seemingly adequate cardiac output and arterial blood pressure.[†] In humans, the activation of neutrophils after trauma, with increased adhesion molecule expression and propensity for degranulation, is associated with morbidity after trauma, such as development of MOF and predisposition to sepsis.^{115-117,233,237,247} After initial leukopenia (neutropenia) following trapping of leukocytes in the microcirculation, activation of the pituitary-adrenal axis and release of corticosteroids and catecholamines during hypovolemic shock result in an increase of circulating neutrophils following demargination and release from bone marrow, together with eosinopenia and lymphocytopenia.^{46,112-115,216} A tertiary decrease of circulating neutrophils in patients with a downhill course may be explained by microcirculatory sequestration.¹¹⁵ The hemodynamics, organ function, and survival of rats with hypovolemic shock/resuscitation are improved if rats are made neutropenic before the challenge, and this may relate to improved regional and capillary blood flow.^{112,243} A monoclonal antibody against or antagonists of neutrophil-endothelial adhesion molecules decrease reperfusion injury in lungs, liver, stomach, and intestines after hypovolemic shock or ruptured aortic aneurysm and may improve survival, at least in animal models.^{114,117,118,187,228} This does not impair host defense against subsequent bacterial infections.¹¹⁴

However, neutrophils may later become downregulated after initial stimulation by circulating proinflammatory and anti-inflammatory mediators.^{111,229,248} Neutrophil dysfunction is evidenced by a diminished potential to migrate and to digest and kill bacteria, perhaps in the presence of an inhibited respiratory burst.^{111,188,247,248} In hemorrhaged mice, the infusion of granulocyte colony-stimulating factor or IL-6 after hemorrhage may partly prevent neutrophil defects and protect against death from subsequent pulmonary sepsis.²⁴⁸ Also, the opsonization function of macrophages, that is, the

*166, 186, 187, 193, 216, 230, 235-237

†54, 193, 204, 205, 238-241

*10, 113, 114, 116, 151, 166, 188, 198, 216, 228, 240, 242, 244

†46, 79, 95, 112, 114, 206, 243

reticuloendothelial system, is depressed so that removal from the circulation of fibrin, cell aggregates, and bacteria by the liver is at least transiently impaired.* This may relate to the appearance after hypovolemic/traumatic shock of substances in blood that depress reticuloendothelial system function or to a decrease of the α_2 -glycoprotein fibronectin in plasma, a substance that aids the reticuloendothelial system in opsonization.^{4,167,236,249,251} This deficiency may contribute to development of MOF and might be reversed by infusion of plasma cryoprecipitate.²⁵¹ Hypovolemic shock and gut-derived factors may blunt the increase in bone marrow cytopoiesis after soft tissue trauma and endotoxin and contribute to susceptibility to sepsis.^{252,253}

Hemorrhagic/hypovolemic shock and subsequent resuscitation depress the immune system by suppressing the function of not only neutrophils but also lymphocytes and macrophages; this depresses humoral and cellular immune responses, decreasing antigen presentation and delayed hypersensitivity to skin test antigens and increasing susceptibility to sepsis.[†] Part of this may be mediated via neuroimmune modulation and resulting efferent sympathetic, adrenergic, and vagal stimulation.^{37,93} In patients, the immune defect correlates with the extent and severity of trauma and the degree of blood resuscitation required, but animal experiments document that hemorrhage/resuscitation per se depresses immune function, although trauma and blood transfusions may only be synergistic in this respect.^{236,250,254,255,258} Priming of immune cells may explain in part the increased sensitivity to endotoxin and sepsis after hypovolemic shock, although other authors have described that prior hypovolemic shock and priming decreased the immune response and increased the tolerance to endotoxin or sepsis.^{114,184,187,259} Hemorrhage decreases the capability of lymphocytes to proliferate and to produce lymphokines (IL-2) in response to mitogens, an effect that seems dependent on an energy or NO deficit or on Ca^{2+} influx in these cells after ischemia because the defect can be overcome by administration of Ca^{2+} influx blockers.^{236,250,254,255,258} Increased macrophage production of cytokines during hypovolemic shock and resuscitation may be followed by decreased ability of the cells to release mediators such as $\text{TNF-}\alpha$ and to express HLA-DR, upon challenges, and to process and present antigens to lymphocytes. This may relate to a cellular energy deficit, accumulation of Ca^{2+} , and enhanced prostaglandin E_2 synthesis.[‡] The immunodepression after hypovolemic shock and predisposition to sepsis may finally include the release by Kupffer cells, among others, of anti-inflammatory mediators, such as IL-10 and soluble receptors (receptor antagonists) for previously released proinflammatory cytokines, and this may relate to sepsis-induced MOF and increased risks of morbidity and mortality in trauma patients.^{250,260} Otherwise, the immunologic consequences of trauma, hemorrhage, and hypovolemic shock depend on numerous additional factors, including gender and other genetic influences.^{230,247,250} Men may exhibit more immunodepression after trauma/hemorrhage than women. The clinical implication may be that men

are more susceptible than women to microbial infections after trauma.²⁶¹

Circulating coagulation factors and platelet counts may decrease after hypovolemic shock and resuscitation, whereas fibrin products may increase. This is the consequence of coagulation activation and fibrinolysis inhibition by endothelial activation, tissue injury, and inflammatory responses, even though dilution after fluid resuscitation may heavily contribute.^{181,237,262} Disseminated intravascular coagulation (DIC) and fibrin deposits, if insufficiently removed by the fibrinolytic system, are believed to contribute to a decrease in plasma coagulation factors and to widespread microvascular organ dysfunction.^{181,237,263} Proinflammatory responses, some resuscitation fluids, hypothermia, and acidosis may contribute to DIC and the coagulation defect of severe hemorrhagic/traumatic shock.^{237,264}

REPERFUSION AND IRREVERSIBLE SHOCK

Reperfusion of various organs, including the heart, gut, skeletal muscle, brain, kidneys, and liver, after a transient episode of ischemia, as occurs during hypovolemic shock, results in the so-called reperfusion injury, which limits the possibility for resumption of microvascular tissue blood flow and function of organs, particularly of the liver, even if cardiac output and arterial blood pressure have been restored to normal value.* Redistribution of blood flow during hypovolemia may be only partly attenuated by reperfusion.

Reperfusion after a certain period of shock and diminished oxygen uptake results in an increase in oxygen uptake above baseline levels, provided that oxygen delivery and cellular function are adequate.^{42,62,73,99} This repayment of the oxygen debt is largely determined by the increased demands for oxygen to resynthesize ATP from adenosine and phosphates and to rebuild the lost energy stores. This repayment is determined by the extent to which mitochondria are damaged during ischemia and the availability of substrates to resynthesize high-energy phosphates and restore cellular contents of these compounds because the substrates needed for synthesis may have been washed out, necessitating de novo synthesis.^{24,142,143} Resuscitation may not completely restore energy levels, the activity of the Na^+/K^+ pump, and the membrane potential of skeletal muscle and liver necessary to remove accumulated fluid and Na^+ in the cell.^{125,127,142}

Reperfusion not only results in resumption of oxygen delivery but also of Ca^{2+} to the tissues. This Ca^{2+} may be taken up by cells and may contribute to the reperfusion injury by damaging cell organelles, inhibiting mitochondrial respiration, and activating proteases and prostaglandin synthesis.^{127,129,148,149} Reperfusion injury of heart, gut, kidneys, and liver after resuscitation from hypovolemic shock in animals may be prevented in part by administration of Ca^{2+} influx blockers independently of their vasodilating effects, suggesting that Ca^{2+} overload is partly responsible for the reperfusion injury.^{127,129,148,149} Finally, endothelial damage and swelling and cellular aggregation may hamper the regional regulation of blood flow during resuscitation from

*4, 24, 167, 236, 249, 250

†2, 111, 235, 236, 247, 248, 250, 253–257

‡166, 235, 236, 247, 250, 256

*79, 114, 144, 149, 166, 199, 206, 215, 228, 265, 266

hypovolemic shock.^{79,95,110,122} Neutrophil-mediated endothelial injury may increase capillary permeability and contribute to fluid losses during resuscitation.^{112,178,179,228,267} Conversely, the intravenous administration of energy in the form of ATP-MgCl₂ or adenosine-regulating compounds may help tissues to recover from ischemia and resume function, independently of the vasodilating effects of the compounds, by providing energy, improving the microcirculation, and reducing cell swelling to promote survival.* Nevertheless, the ability of organs or the whole body to increase oxygen uptake during reperfusion above normal may be associated with survival in experimental animals with hypovolemic shock and in hypovolemic patients after trauma or major surgery, whereas inability may be associated with ultimate demise.^{9,73,82} Also, ischemic preconditioning may protect against hemorrhagic shock and reperfusion-induced tissue injury.¹⁵⁶

If shock syndrome with hypotension and subnormal oxygen uptake persists after optimal fluid repletion and attempts at reperfusion with inotropic and vasoactive drugs, the condition can be regarded as irreversible and terminal.^{4,9} The term *irreversible shock* has been mainly used in animal experiments, however, in which reinfusion of the shed blood after a certain period is unable to reverse the shock syndrome.^{4,268} Various factors may play a role.⁴ First, vascular decompensation may contribute to a further decrease in blood pressures and may include diminished constrictive reactivity, dilation of arterioles, and insensitivity to circulating or exogenous catecholamines.^{97,108} The decline in vascular resistance may be partly caused by metabolic vasodilation in ischemic and acidotic tissues, overcoming vasoconstrictive influences.^{4,10,108} Other factors that may be involved include dysfunction of vascular smooth muscle after induction of iNOS and resultant increased production of vasodilating NO in the vessel wall, acidosis and activation of low ATP-activated K⁺ channels, histamine release, and prostaglandin-induced neurotransmission failure.[†] Circulating levels of NO breakdown products, nitrate and nitrite, may be elevated already early after hemorrhage in animals and trauma in humans, although other authors described low levels in humans.²⁶⁹ iNOS upregulation and NO production may be prevented by NO blockers, corticosteroids, or ACTH fragments.^{92,93,229} Finally, central cerebral or humoral mechanisms may contribute to the irreversible hemorrhagic shock, and this may relate to endogenous opioids, thyrotropin-releasing hormone, or macrophage-derived cannabinoids.^{13,23,270}

The decrease in arterial vascular resistance may be particularly pronounced in the tissues, showing most intense vasoconstriction during hypovolemic shock, including gut and skeletal muscle, offsetting the redistribution of blood flow during hypovolemic shock and increasing blood flow to these organs at the expense of blood flow to vital tissues.^{10,22} In contrast, venous compliance and resistance increase, leading to peripheral pooling of blood and a decrease in venous return to the heart.^{4,166} The latter changes may be particularly pronounced in the splanchnic region.¹⁶⁶ During prolonged or irreversible hypovolemic shock, capillary hydrostatic pressure may

increase after arteriolar vasodilation and venular constriction, resulting in a decrease in the precapillary-to-postcapillary resistance ratio and promoting fluid filtration into the interstitium.^{4,5} Capillary permeability also may increase, resulting in a high capillary hydraulic conductance and a decrease in the reflection coefficient for plasma proteins. Increased permeability for proteins increases capillary filtration for a given intravascular hydrostatic pressure and promotes the formation of edema.^{178,267} The increase in permeability may be the consequence of endothelial damage and loss of protective glycocalyx by ischemia-reperfusion, possibly involving ROS and proinflammatory mediators.²⁷¹ It may contribute further to a decline in circulating blood volume.^{5,267} Cells may swell, and this may diminish circulating blood volume further.^{4,125,127-129} Expansion of the cellular and interstitial fluid volume at the expense of the intravascular volume is manifested by a preterminal increase of the hematocrit.^{4,5,126}

Irreversible hypovolemic shock may contribute to MOF and death of patients.^{2,207} An inflammatory response to ischemic tissue and patchy necrosis/apoptosis may contribute to organ damage and dysfunction and thereby to the irreversibility of hypovolemic shock.^{4,114,228} Reperfusion injury may aggravate organ damage and contribute to irreversible shock.^{114,228,266} The pump function of the heart may diminish after a decrease in systolic contractility and compliance, and this may contribute to irreversibility of shock during resuscitation.¹⁵⁸ Myocardial dysfunction may contribute to the development of pulmonary alveolar edema if aggressive fluid infusion in attempts to increase cardiac output results in an elevated PCWP.⁴ Diminished function of the heart may hamper restoration of oxygen delivery and uptake to the tissues during resuscitation.^{9,45,157,158} Damage of the gut mucosa may cause translocation of luminal bacteria and endotoxins from gut lumen to systemic circulation, at least in experimental animals, and the resultant sepsis may contribute to the irreversibility of hypovolemic shock.*

CLINICAL FEATURES

CAUSES

One of the most frequent causes of hypovolemic shock is blood loss after trauma (see [Box 26.1](#)), including blood loss during or after major surgery.² Ruptured aortic aneurysm and gastrointestinal hemorrhage are other frequent causes of hypovolemic shock. Upper gastrointestinal bleeding can be caused by peptic ulcer disease, reflux esophagitis, variceal bleeding, erosive gastritis (stress ulcer), or aortoduodenal fistula after vascular surgery. Lower gastrointestinal bleeding can result from diverticular disease, carcinomas, or polyps in the colon. Sometimes, massive hemoptysis resulting from a tumor, tuberculosis, fungal infection, or bronchiectasis can be the cause of hypovolemic shock. Hematuria as a result of a tumor or trauma is a rare cause of hypovolemic shock. During multiple trauma, blood loss is essential in causing hypovolemic shock, but trauma itself can activate various mediator systems, with resultant release

*24, 128, 143, 144, 158, 230

†10, 29, 92, 93, 96, 97, 139, 229, 242

*4, 185, 197, 199, 202–205, 214

of vasoactive substances that contribute to the development of shock. In contrast to pure hypovolemic shock, cardiac output can be elevated, and peripheral vascular resistance is often decreased in cases of multiple trauma.²⁵

In trauma patients, external blood loss can be accompanied by internal, invisible blood loss after renovascular trauma or major fractures (e.g., fractures of pelvis or femur). After blunt abdominal trauma, splenic or hepatic ruptures and perforations of hollow viscera are possible. Blunt chest trauma can be accompanied by an aortic rupture, tension pneumothorax, hemothorax or hemopericardium, and tamponade. Femoral artery injury (after puncture) can lead to massive retroperitoneal hematoma. Nonmechanical causes of hypovolemic shock include uncontrolled diabetes mellitus and acute adrenocortical insufficiency, causing severe renal fluid losses. Acute and severe vomiting following obstruction of the gastric outlet or gut, diarrhea, and burn wounds result in loss of plasma water.

SIGNS AND SYMPTOMS

Hypovolemic shock warrants an early diagnosis, avoiding delay in initial treatment. As soon as possible after admission of the patient, fluid resuscitation should begin via a large-bore catheter in a peripheral vein or a percutaneously inserted central venous catheter. During initial fluid resuscitation a history is taken and a brief but thorough physical examination is performed. The latter serves to establish rapidly the cause and severity of shock. Extensive manipulation of a fractured spine or extremity should be avoided. The history of a patient in hypovolemic shock is mainly determined by its cause. The patient may complain of thirst, diaphoresis, and shortness of breath. The patient's mental state is usually normal unless shock is severe and the patient becomes apathetic or confused. With less severe cases, the patient is anxious, and with more severe cases, the patient is apathetic.

For a clinical diagnosis of shock, hypotension and clinical signs of organ ischemia should be present. Arterial blood pressure and clinical signs are relatively insensitive for small blood losses (Table 26.1).²⁰⁸ This sensitivity can be improved by using the shock index, calculated from heart rate divided by systolic blood pressure.¹⁸ The clinician can recognize shock from a decrease in systolic blood pressure to less than 90 mm Hg or a decrease of more than 40 mm Hg below

preshock levels, with a reduction in pulse pressure. Hypotension may be so severe that blood pressure is unrecordable noninvasively. There can be a large gradient between invasively and noninvasively measured arterial blood pressure and between central and radial artery pressure during shock and drug-induced vasoconstriction.²⁷² Hypotension may become particularly marked when the patient sits or stands versus when the patient is supine (orthostatic hypotension).^{8,17,18} Postural dizziness, tachycardia, and hypotension are reliable and early signs of hypovolemia, whereas dryness of mucous membranes and axillae, decreased turgor, supine hypotension, and other signs have less diagnostic value.^{17,18}

Tachycardia may be absent in case of prior use of beta blockers. Elderly patients may have atrial fibrillation and a high ventricular response. Occasionally, bradycardia is present, particularly when vagally mediated fainting supervenes.¹⁶ The peripheral veins are collapsed, and the jugular venous pressure is low. Conversely, an elevated jugular venous pressure should warn the clinician of associated obstruction of the circulation, following pneumothorax, pericardial tamponade, and others, or of pump failure following myocardial contusion or infarction. The respiratory cycle-induced changes in stroke volume and in systolic arterial blood pressure and CVP are exaggerated.²⁰ Although dependent on tidal volume and respiratory compliance, these variations in a mechanically ventilated patient may constitute fair indices of hypovolemia, so high variations may predict an increase in cardiac output upon fluid loading.¹⁹ Noninvasive, pulse contour-based techniques are suitable for these purposes. Fluid responsiveness also can be predicted by an increase in blood pressure and decrease in stroke volume and pressure variations during leg raising or similar maneuvers. The body temperature may decrease, particularly in elderly patients. The gradient between the ambient and toe temperature may be a fair index of peripheral blood flow and a measure for the severity of hypovolemic shock because a reduction in skin blood flow (cold, clammy skin) is an early and ominous sign of shock in view of selective cutaneous vasoconstriction.¹²³ Other signs of hypovolemic shock include tachypnea, oliguria/anuria, diaphoresis, cold and clammy skin with diminished capillary refill, and peripheral cyanosis.

The clinical diagnosis of hypovolemic shock is not difficult in the presence of hypotension and visible loss of

Table 26.1 Clinical Classification of Severity of Posthemorrhagic Hypovolemic Shock

Feature	Class I	Class II	Class III	Class IV
Blood loss				
mL	<750	750-1500	>1500-2000	>2000
%	<15	15-30	>30-40	>40
Heart rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14-20	20-30	30-40	>40
Urinary output (mL/h)	>30	20-30	5-15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (mL/h)	Crystalloid	Crystalloid/colloid	Crystalloid and blood	Crystalloid and blood

blood volume, as occurs during trauma (e.g., fractures), gastrointestinal or pulmonary hemorrhage, burn wounds, and diarrhea. Internal hemorrhage after a ruptured aortic aneurysm, blunt abdominal trauma, or hemothorax is difficult to diagnose except when the history of the patient and obvious physical signs, including dullness on thoracic percussion and abdominal distention and tenderness, point to potential internal bleeding. In the case of upper gastrointestinal blood loss, one should look for signs of chronic liver disease, including palmar erythema, spider nevi, and portal hypertension (ascites), because they could predict variceal bleeding as a cause of hypovolemic shock. Brown discoloration of the palms of the hands and mucosal membranes may point to adrenocortical insufficiency, and a smell of acetone in expiratory breath may point to uncontrolled (ketoacidotic) diabetes mellitus.

DIAGNOSTIC APPROACH

GENERAL

The diagnostic workup of a patient with hypovolemic shock should not hamper initial resuscitation. After the history and physical examination, the necessity for further diagnostic procedures depends on the underlying cause of shock.

If trauma and external blood loss are the cause of shock, control of external bleeding, crossmatching of blood, and infusion of fluids and blood components have a higher priority than further diagnostic procedures. Treat first what kills first. Blunt chest trauma can be complicated by aortic rupture, tension pneumothorax, hemothorax or hemopericardium, and tamponade. A chest radiograph can be useful to diagnose these conditions. After blunt abdominal trauma, splenic or hepatic ruptures are possible, and an abdominal tap and analysis of the fluid can be performed to exclude or establish intra-abdominal bleeding or hollow-organ perforation.^{273,274} This diagnostic procedure has been largely replaced, however, by imaging, if time permits, with help of so-called focused assessment sonography for trauma (FAST) or computed tomography of the abdomen in the emergency department. This helps in selecting patients for explorative laparotomy in order to avoid negative surgery or for percutaneous coiling.^{273,274} The abdominal viscera show characteristic lesions in hemorrhagic shock with low filling of large veins, decreased perfusion of some organs, wall thickening, submucosal edema, and enhancement of the gut.²⁷⁵ A ruptured abdominal aortic aneurysm can be diagnosed via ultrasonography or angiography if the patient's condition allows the use of such an invasive, time-consuming procedure. The usefulness of emergency aortic clamping or balloon tamponade for massive abdominal hemorrhage is controversial.²⁷⁶ In the case of gastrointestinal hemorrhage, diagnostic procedures also are performed after initial resuscitation, including gastroscopy for upper gastrointestinal bleeding, sigmoidoscopy for lower gastrointestinal bleeding, and angiography. Introduction of a nasogastric tube (and early intubation) can be useful to aspirate blood, diagnose bleeding, prevent aspiration during vomiting, and follow the course of bleeding.

LABORATORY INVESTIGATIONS

At admission of a patient with suspected hypovolemic shock, blood samples should be taken to determine the hemoglobin/hematocrit and leukocyte and platelet counts; electrolyte, creatinine, and lactate concentrations; arterial blood gases and pH; and blood typing (crossmatching). Immediately after hemorrhage, the hemoglobin content and hematocrit of blood are normal, but they decrease in time with refilling of the plasma compartment, as does the protein content.* A high hemoglobin content and hematocrit can be encountered during pure loss of plasma (water), as occurs during burn wounds or severe diarrhea. Acute hypovolemic shock may be accompanied by slight leukopenia followed by leukocytosis.^{46,111,112,248,253} If coagulation disorders are suspected (therapy with anticoagulants, liver disease, bleeding tendency), platelet counts and coagulation tests should be performed. Transient thrombocytopenia may ensue if shock is severe and massive amounts of whole blood are lost and rapidly replaced by erythrocyte concentrates or nonsanguineous fluids (i.e., through dilution). Isolated thrombocytopenia without DIC may thus occur.

The concentrations of electrolytes (sodium, potassium, chloride) in blood are essentially normal unless the concentrations in the fluid lost deviate from those in plasma (hypertonic and hypotonic dehydration) and resuscitation fluids and shock is accompanied by severe metabolic acidosis. In the latter example, potassium leaves the cell, potentially leading to hyperkalemia.^{111,125} More often, however, less severe forms of shock are accompanied by hypokalemia because of adrenergic receptor-stimulated Na^+/K^+ -ATPase. Saline fluid loading or overloading can result in hyperchloremic metabolic acidosis. Adrenocortical insufficiency may result in hyponatremia, hyperkalemia, and hyperchloremic acidosis, caused by changes in urinary excretion induced by mineralocorticoid deficiency. In a patient with liver disease, the corresponding abnormalities can be found in laboratory studies. In the case of uncontrolled diabetes mellitus, hyperglycemia and glucosuria are observed. As previously mentioned, the glucose concentrations in blood can be elevated in early shock and, occasionally, depressed in late shock. Finally, the concentration of unbound Ca^{2+} in blood may diminish during hypovolemic shock after cellular uptake and polytransfusion of red blood cell concentrates if they contain calcium-binding citrate as an anticoagulant.^{127,150}

During hypovolemic shock, metabolic acidosis, often associated with an elevated lactate level in blood, is common and of prognostic significance, although the decrease in bicarbonate and base excess may not parallel the increase in lactate.^{27,31-33,38,41} The pH can be subnormal after lactic acidosis and a decrease in the bicarbonate content, even if ameliorated by hyperventilation and a decrease in Pco_2 .^{27,32,33,49,50} The lactate level in blood can be determined rapidly and followed frequently (every 2 hours). The lactate level and its course during treatment also is of prognostic significance during shock because during successful treatment the lactate level decreases and the bicarbonate concentration and pH increase, whereas an unchanged or even increased lactate level during resuscitation is usually

*126, 132, 133, 137, 182, 183, 277, 278

associated with morbidity, including sepsis, MOF, and death.^{27,31,32,56} An elevated anion gap, the difference between the sodium on the one hand and the sum of the bicarbonate and chloride concentrations in blood on the other hand, can be a first sign of lactic acidosis, although, as previously mentioned, elevated lactate levels may not be associated with acidosis in the absence of an oxygen debt.²⁷ The serum creatinine concentration is initially normal. The urea content increases following prerenal renal insufficiency, catabolism, or breakdown of blood in the gut during gastrointestinal hemorrhage. In the urine, the osmolality is increased.

The sodium content is low, together with a low fractional excretion of sodium (FE_{Na}),¹³⁸ calculated as the quotient of urinary (U) and plasma (P) sodium (Na) and creatinine (creat) concentrations:

$$FE_{Na} = (U_{Na}/P_{Na})/(U_{creat}/P_{creat})$$

In case of acute renal injury (acute tubular necrosis), the urinary sodium content and fractional excretion are increased.¹³⁸ This increased sodium also occurs during adrenocortical insufficiency. Prior diuretic therapy may invalidate this diagnostic tool, however, whereas the fractional excretion of urea may not be affected by diuretics.¹⁰⁴ Tubular injury may be tracked from increased urinary excretion of biomarkers, which may help predict the need for renal replacement therapy.¹⁰⁴

Miscellaneous abnormalities may include elevated levels of nitrate and nitrite, the stable breakdown products of NO.²⁶⁹ Transient elevations of bilirubin, alkaline phosphatase, γ -glutamyltransferase, and transaminases in blood may be severe and denote ischemic liver damage.^{222,223} Elevations of creatinine kinase may be caused by skeletal muscle, cardiac, gut, or, less likely, brain damage. Elevated troponin concentrations may specifically indicate cardiac injury.^{163,173}

MONITORING

Noninvasive monitoring of arterial blood pressure to judge the course of shock and its response to treatment suffices for some patients with hypovolemic shock. Nevertheless, there may be substantial differences between the invasive and noninvasive readings of arterial blood pressure, favoring arterial catheterization and invasive monitoring. Urinary output should be measured hourly in patients with shock to judge the adequacy of treatment because transition of oliguria to a diuresis exceeding 40 mL/hour is an indicator of adequate renal perfusion. The gradient between toe and body temperature and capillary refill time can be used as noninvasive indices of peripheral perfusion.¹²³

Unless hypovolemic shock is rapidly reversed by initial infusion of fluids, there is often a need for hemodynamic and respiratory monitoring in the intensive care unit for a patient with hypovolemic shock. The goal of monitoring is to document the course of shock and its reaction to treatment. Complications can be diagnosed in an early phase so that action can be rapidly undertaken, if necessary. Respiratory monitoring is meant to detect, at an early stage, respiratory insufficiency and muscle fatigue, which are caused by an imbalance in oxygen supply to demand and which may necessitate intubation and mechanical ventilatory support.⁵⁰

Arterial blood pressure can be monitored invasively via a catheter in the radial, axillary, or femoral artery, introduced percutaneously using the Seldinger technique, under aseptic conditions. Percutaneous insertion of a double-lumen or triple-lumen central venous catheter may be useful but does not allow for more rapid fluid infusion than through two peripheral cannulas. The internal jugular, subclavian, or femoral vein may be used for that purpose. This also permits monitoring of CVP and oxygen saturation and a measure of total body oxygen supply-to-demand ratio and predictor of fluid responsiveness. Pressures in the lesser circulation (pulmonary arterial pressure and PCWP) can be measured with the help of a balloon-tipped pulmonary artery catheter inserted percutaneously and advanced under pressure monitoring until the inflated balloon wedges in a pulmonary artery side branch. This catheter also allows for thermodilution measurement of cardiac output and obtaining mixed venous blood for blood gas analysis.^{73,279} Together with arterial blood measurement of oxygen variables, this allows the calculation of oxygen delivery, extraction, and uptake.^{9,25,73} These calculations may contribute to judging the severity of shock and its response to treatment.^{6,9,25,73}

The CVP reflects the filling pressure of the right ventricle, and the PCWP reflects the left atrial pressure and, in the absence of mitral valve disease, the filling pressure of the left ventricle.¹⁹ Under certain circumstances, however, including ventilation with positive end-expiratory pressure or measurement above the level of the left atrium, when the measured pressure is more influenced by alveolar than by venous pressure, the CVP and PCWP may overestimate true (i.e., transmural) right and left atrial pressures. The response of filling pressure and cardiac output to fluid loading, as measured with the central venous or pulmonary artery catheter, is an index of myocardial function and can be useful to assess fluid responsiveness, particularly in case of preexistent and prognostically unfavorable cardiac disease.* Measurement of PCWP is important if function or compliance of the left ventricle is altered (e.g., in case of preexistent heart disease), when the CVP may underestimate PCWP.^{55,71} Conversely, the CVP may overestimate PCWP in cases of severe pulmonary hypertension and right ventricular failure. It has been suggested that changes in CVP during fluid loading do not predict changes in PCWP.⁷¹ The intensity and speed of therapy can be guided by the response of filling pressures and cardiac output, as measured with the use of the central venous or pulmonary artery catheter.^{9,19,31,42,55}

These measurements also can help to time, choose, and dose concomitant therapy with inotropic or vasopressor agents. Together with the plasma colloid osmotic pressure, the PCWP determines filtration of fluid across pulmonary capillaries according to the Starling equation. Monitoring of the PCWP during infusion of fluids may prevent pulmonary edema because infusion can be guided by the filling pressures of the heart. Taken together, data obtained with the pulmonary artery catheter are useful if the hypovolemic origin of shock is not immediately apparent in complicated cases, as in patients with preexistent cardiac disease.^{9,25,73} Data obtained with the catheter are of diagnostic value in complicated forms of shock because hypovolemic shock is

*19, 20, 55, 71, 159, 171

characterized by low filling pressures and cardiac output and a high peripheral vascular resistance. These characteristics may serve to differentiate from other types of shock. The indications for insertion may also include a high risk for shock in patients undergoing major surgery and shock of unknown origin when clinical judgment fails to recognize severe hypovolemia.

Difficulties during treatment also may constitute indications for pulmonary artery catheterization, including hypovolemic shock unresponsive to liberal fluid repletion in the absence of a low jugular venous pressure or CVP and hypovolemic shock together with preexistent cardiac disease unresponsive to fluid repletion if a large discrepancy between CVP and PCWP is suspected and if vasoactive drugs are considered. Monitoring the PCWP may help to lessen the risk for pulmonary edema during fluid loading. Contraindications for pulmonary artery catheterization include those for central venous catheterization. The complications of the technique are discussed elsewhere. Although the use of pulmonary artery catheters is hotly debated because of lack of direct evidence that they help to increase survival, there are some indications that therapy guided by variables collected with the catheter improves the outcome of selected critically ill patients after trauma or surgery.^{9,25,73,280} Nevertheless, the exact hemodynamic and metabolic resuscitation goals are difficult to define, so the usefulness of the pulmonary artery catheter is difficult to prove.^{9,26,42,67,280}

As an alternative to invasively inserted catheters, various less invasive or even noninvasive (pulse contour–based) systems have been developed that circumvent some of the problems associated with filling pressures as preload indicators and predictors of responsiveness of cardiac output to fluid loading.^{19,20,281} Among others, the transpulmonary thermodilution technique with detection of thermal changes after central venous injection of cold dextrose 5% in water in the iliac artery allows for calculation of cardiac output, global end-diastolic volume, and extravascular lung water—measures of cardiac preload, pulmonary fluid filtration, and edema.²⁸¹ Assessment of cardiac volumes can be helpful to judge function, similar to echocardiography.^{157,281} The latter technique also evaluates filling or injury of large vessels, suspected cardiac contusion, and pericardial tamponade.²⁸² The diameter (changes) of the large veins can be used as an indicator of filling status. The use of pulse-contour techniques for beat-to-beat evaluation of arterial pressure curve–derived stroke volume, as well as pulse pressure and stroke volume variations invoked by the respiratory cycle to guide fluid treatment in mechanically ventilated patients, remains controversial.^{20,281} The esophageal Doppler flow probe with which flow time, stroke volume, and cardiac output can be estimated is somewhat operator dependent.

Developments in monitoring the circulation of a patient in hypovolemic shock further include continuous monitoring of central venous or mixed venous oxygen saturation with the help of the fiber-optic technique introduced via catheters, allowing for the continuous evaluation of the oxygen supply-to-demand ratio; right ventricular end-diastolic volume monitoring as an index of filling status; and measurement of tissue blood flow, PO_2 , PCO_2 , and oxygenation by electrodes and optic techniques.* Venous O_2

saturation may indeed help to guide fluid resuscitation in clinical practice because a low saturation increases upon adequate fluid challenges in fluid-responsive patients. Tissue PO_2 decreases and PCO_2 increases during regional perfusion failure, and these events (in skin, conjunctiva, muscle, or bladder) are probably early signs of hypovolemia following redistribution of blood flow before hypotension ensues and have been used as guides to treatment.* The adequacy of gastrointestinal blood flow can be judged noninvasively with the help of a tonometer balloon catheter in the stomach (or gut) or with help of a sensor sublingually or buccally, in which fluid or air is instilled, and the PCO_2 is measured to calculate the mucosal-to-blood PCO_2 gradient, as explained previously.[†] Fluid treatment guided by the adequacy of gastrointestinal mucosal perfusion as judged by tonometry could improve the outcome of hemorrhaged trauma patients compared with resuscitation based on standard hemodynamic variables alone.^{40,123,209,211}

Monitoring the end-tidal CO_2 fraction, determined by and directly related to the blood flow–dependent tissue CO_2 production, and the gradient to arterial PCO_2 , determined by blood flow–dependent dead-space ventilation, can help to judge the response to resuscitation.^{49,65} Hydrostatic pressure measurements in the urinary bladder may reflect the measurements in the abdominal compartment and may help to identify intra-abdominal hypertension and abdominal compartment syndrome developing during extensive fluid resuscitation.²⁸⁵ This may impair gut and renal perfusion with subsequent dysfunction and warrant decompression laparotomy.²⁸⁵

APPROACH TO MANAGEMENT

GENERAL

Treatment of shock cannot be delayed, so in practice diagnosis and treatment are done simultaneously. Treatment of hypovolemic shock is aimed at the restoration of the circulation and treatment of the underlying cause. **Box 26.2** describes some general guidelines, but we do not specifically address burn wound shock requiring a special approach. The main therapeutic goal in hypovolemic shock is to restore circulating blood volume and to optimize oxygen delivery so that oxygen uptake plateaus (see **Fig. 26.1**) and meets tissue needs.^{72,286} Optimization of cardiac output, stroke work, and tissue oxygenation and maintenance of arterial blood pressure are physiologically reasonable resuscitation targets for patients.⁴² Optimization does not imply maximization above levels adequate for tissue needs.^{26,67} Studies by some investigators have suggested that supranormal rather than normal oxygen delivery and consumption may be associated with survival from severe trauma or hemorrhage, including a ruptured aortic aneurysm, and that therapeutic targeting at these values (with oxygen delivery >600 mL/minute/ m^2 and oxygen consumption >170 mL/minute/ m^2) improves the outcome of severe trauma in humans.^{9,25,40,42,83} These concepts are highly controversial, however. In any case, resuscitation based on blood pressure

*30, 44, 48, 53, 59, 68, 123, 145, 209, 283, 284

*8, 44, 48, 59, 68, 123

†40, 54, 68, 92, 106, 139, 166, 196, 208, 210, 211

Box 26.2 Guidelines for Treatment of Hypovolemic Shock

1. Insert large-bore intravenous catheter; perform laboratory investigations (crossmatching, hemoglobin/hematocrit, platelet count, electrolytes, creatinine, arterial blood gas analysis and pH, lactate, coagulation parameters, transaminases, albumin). Watch for need to supply oxygen, intubation, or artificial ventilation (so that arterial $PO_2 > 60$ mm Hg and oxygen saturation $> 90\%$).
2. Resuscitation with fluids is done primarily with crystalloids, sometimes colloids. At $>25\%$ loss of blood volume, give erythrocyte concentrates; at $>60\%$ loss, also give fresh frozen plasma (e.g., after about three erythrocyte concentrates and earlier in case of massive bleeding or disturbed coagulation). In case of polytransfusions ($>80\%$ loss) and platelet counts <50 (<100 in massive and intracranial bleeding) $\times 10^9/L$, platelet suspensions should be given. Massive red blood cell transfusion is preferably performed via microfilter. Also consider antifibrinolytics and fibrinogen.
3. Diagnose and treat underlying cause, concomitantly with guideline 2.

alone probably does not fully restore tissue oxygenation, particularly in the case of myocardial dysfunction after shock and resuscitation.^{42,55}

Adequate resuscitation from hypovolemic shock should result in an increase in oxygen delivery and uptake, a decrease in lactate levels, and amelioration of metabolic acidosis.* Concomitantly with the increase in cardiac output, arterial blood pressure increases, but normal levels may not be necessary to aim at during resuscitation.^{71,72,172} Indeed, successful resuscitation in terms of a restored cardiac output and arterial blood pressure may poorly reflect effective recovery of tissue perfusion, even though reversal of oliguria is considered a favorable return of renal perfusion.† Animal experiments have suggested that early circulatory optimization also ameliorates inflammatory changes after trauma/hemorrhage. In attempts to restore oxygen delivery, hypoxemia should be prevented or corrected, although recent evidence suggests that hypoxic resuscitation ameliorates proinflammatory responses to reperfusion as compared to normoxic resuscitation.²³⁴ The arterial oxygen saturation, important for the oxygen content of delivered blood, usually exceeds 90% if the PO_2 is greater than 60 mm Hg. If arterial PO_2 is less than 60 mm Hg, supplemental oxygen can be given through a nasal cannula or mask, but hyperoxemia should be avoided. The patient should be intubated and artificially ventilated in case of impending respiratory insufficiency from whatever cause. Prophylactic positive end-expiratory pressure in attempts to prevent the development of ARDS in at-risk patients, including patients with traumatic/hemorrhagic shock, is useless.

For the initial stabilization of trauma patients in shock with severe abdominal trauma or bleeding from lower extremities, passive leg raising or Trendelenburg positioning has been used, but a large benefit on preload-augmented

tissue oxygen delivery has been doubted.^{8,19,20,287} The pneumatic antishock garment can be applied as a temporary, immediately lifesaving procedure to (1) stop the hemorrhage and splint pelvic and lower extremity fractures for transportation of the patient after inflation, (2) mobilize blood volume by exerting external pressure on the leg and abdomen, and (3) redirect flow toward vital organs such as the heart and brain.²⁸⁸⁻²⁹⁰ Use of the garment and hypertonic saline may act synergistically.²⁸⁸ The disadvantages of the procedure include aggravation of pressure-dependent and uncontrolled bleeding and ischemia of intra-abdominal organs. Deflation should be gradual to prevent lethal hypotension after return into the circulation of vasoactive substances and lactic acid from ischemic tissue.^{288,289} The use of the pneumatic antishock garment has greatly declined in recent decades. Spontaneous breathing against an inspiratory threshold or decreasing expiratory pressure during mechanical ventilation may increase venous return and has been studied experimentally.²⁹¹ Measures to establish a way to the bloodstream for infusing fluids include insertion of a large-bore catheter in a peripheral vein or, if cannulation of peripheral veins seems impossible because of collapse, a catheter in a central (i.e., jugular/subclavian) vein. The latter catheter also allows monitoring of CVP. The intraosseous route for administration of hypertonic fluids is particularly useful in traumatized children with hypovolemic shock.²⁹² To this end, a marrow screw is inserted in the sternum or tibia. Fluids can be given by gravity or pressure.

Further treatment of hypovolemic shock depends on the underlying cause. Immediate surgery is warranted in case of extensive trauma and ongoing internal or external blood loss. Massive intra-abdominal bleeding after blunt or penetrating injury may warrant attempts for control by drug therapy with vasopressin, aortic clamping, or preferably, coiling during a radiologic examination prior to laparotomy for insufficient control. Gastrointestinal hemorrhage can be stopped by conservative treatment, including histamine-2 receptor blockade and endoscopic electrocoagulation or laser coagulation of bleeding peptic ulcers, or coiling of bleeding vessel during angiography. Bleeding varices can be treated by continuous infusion of vasopressin or somatostatin, a Sengstaken-Blakemore balloon tube, endoscopic injection sclerotherapy or banding, or transjugular intrahepatic portosystemic shunt. Surgery is rarely necessary in the institutional presence of experienced intervention radiologists. Apart from fluids, uncontrolled diabetes mellitus necessitates continuous intravenous infusion of insulin (about 6 U/hour). Acute adrenocortical insufficiency warrants administration of steroids (hydrocortisone 100 mg two to four times daily).

RESUSCITATION STRATEGIES

The speed with which shock can be reversed depends on the delay from onset to treatment and the severity of shock, as estimated from the clinical condition and hemodynamic status. The speed of fluid infusion can be guided by the clinical condition of the patient, heart rate and blood pressure, diuresis, and determinations every 2 hours of the arterial blood lactate level and acid-base balance.³¹ Repeated assessment of jugular venous pressure, auscultation of the

†30, 79, 111, 129, 144, 149, 166, 215

lungs, and arterial blood gases are indicated to prevent overhydration and pulmonary edema. If a central venous or pulmonary artery catheter is in place, a fluid challenge protocol can be used (Table 26.2).³¹ Monitoring of central venous or PCWP or preload volumes allows for rapid infusion of solutions and evaluation of the response of oxygen delivery and uptake to resuscitation.^{9,25,31,73} When in doubt, predicting fluid responsiveness in the patient, for instance with cardiac failure on mechanical ventilation, by passive leg raising and other tests that reversibly challenge the circulation can be helpful to further guide fluid therapy and avoid harmful fluid overloading.^{19,20}

The usefulness of immediate and vigorous resuscitation in the course of uncontrolled bleeding (e.g., after penetrating vascular trauma) has been challenged in recent years.^{279,293-295} Studies have shown that infusion of substantial amounts of nonsanguineous fluids and increasing pressure-dependent bleeding lead to dilution of blood components, coagulation disturbances, and increased mortality risk unless the bleeding is controlled before resuscitation.^{279,290,294,295} The clinical implication is that resuscitation

perhaps should not take place, at least not vigorously, at the scene of the accident when bleeding cannot be controlled and transport to the hospital where the bleeding can be controlled is practicable. This may apply not only to trauma patients but also to patients with a ruptured abdominal aneurysm. Authors have proposed slow (low volume) rather than rapid (early and large volume) infusion rates and controlled hypotensive resuscitation (e.g., with help of vasodilators) at least as long as bleeding is uncontrolled.^{290,293,294,296-298} The value of this type of resuscitation in humans with hyperoncotic/hypertonic solutions, including acetate with vasodilating and buffering properties, is debatable.^{210,279,298} Also, the levels of hypotension that are safe remain unclear.²⁹⁹ Conversely, early vasopressor therapy by vasopressin, for instance, may benefit patient outcomes more than large-volume infusions.³⁰⁰ The treatment of massive bleeding by blood products requires an institutional protocol. Closed-loop control of fluid therapy may become clinically applicable in the near future.³⁰¹

FLUIDS

During hypovolemic shock, the repletion of intravascular volume is of primary importance to restore cardiac output and oxygen transport to the tissues before repletion of the interstitial and intracellular fluids.* Available fluids are described in Tables 26.3 to 26.5. Electrolyte solutions (the crystalloid fluids) are shown in Table 26.3, and high-molecular-weight solutions (the colloid fluids) are shown in Tables 26.4 and 26.5. In the first group, the hypertonic fluids (i.e., fluids with a higher osmolarity than plasma) are presented. Among the colloid solutions are solutions with a higher colloid osmotic pressure than plasma—the hyperoncotic solutions. Hypertonic and hyperoncotic solutions are plasma expanders because they are able to mobilize cellular and interstitial fluid during resuscitation and to expand plasma volume rapidly.

Table 26.6 shows how the volume of the various compartments is replenished during fluid resuscitation. Because infusion of glucose 5% hardly increases intravascular volume, this solution has no place in resuscitation from hypovolemic shock. Lactated Ringer's solution containing

K⁺ should not be used during renal insufficiency because of the danger of inducing hyperkalemia. Infusion of lactate-containing solutions during lactic acidosis may be controversial because the capacity of the liver to regenerate bicarbonate from lactate may be impaired.³³ Nevertheless, infusion of lactate-containing solutions such as lactated Ringer's for resuscitation from hypovolemic shock generally does not substantially increase lactate levels, worsen acidosis, or adversely affect outcome.³⁰⁵ However, racemic Ringer's lactate may be proinflammatory and proapoptotic as compared to normal saline and only L-lactate containing solutions are therefore currently recommended.¹⁹¹ Adverse effects of overzealous fluid administration of any type include promotion of pulmonary edema and ascites formation with subsequent aggravation of abdominal compartment syndrome.^{285,286}

The natural colloids consist of albumin and plasma solutions. Albumin is an effective colloidal solution for intravascular volume repletion, and its intravascular half-life is approximately 16 hours.* For the artificial colloids, the volume-expanding effect and the duration of action generally increase with increasing in vivo molecular weight (Table 26.7). About one third of the hyperoncotic fluids with high molecular weight (dextran 70 and hydroxyethylstarch) may still be in the circulation after 24 hours, whereas dextran 40 is retained for approximately 3 hours. Dextran and gelatins are perhaps equally effective in restoring circulating volume.^{309,310} The latter substances might increase tissue blood flow in the microcirculation. Dextran is currently less often used than gelatins and starches and institutional

and geographic habits largely determine the choice among fluids.

The starch compounds have gained wide interest for the resuscitation of hypovolemic shock.* These colloids are at least as effective as albumin but less expensive.^{135,136,172,308,312} Because the molecular range of the starch compounds

varies enormously, the pharmacokinetics are complex.³¹¹ Nevertheless, about 40% of the infused hetastarch (molecular weight >200) still remains in the circulation after 24 hours because 30% of the infused substance may have a half-life of 67 hours. Ninety percent of smaller starch is cleared in 24 hours. The duration of the volume-expanding effect of the starches depends not only on molecular range and concentration but also on the so-called substitution

*62, 136, 170, 303, 304, 308, 311

grade, which is the number of hydroxyethyl groups per glucose unit, and the substitution type, the ratio of C2 to C6 hydroxyethylation.³¹¹ A high molecular weight, high substitution grade, and high C2/C6 ratio retard breakdown by plasma amylase and prolong intravascular retention. The residual starch compounds are partly excreted by urine and partly taken up by the reticuloendothelial system. Accumulation may also occur in dendritic cells of the skin and the liver and in the renal tubules, with subsequent adverse effects. Starch compounds may increase the amylase level in blood and may confound the diagnosis of acute pancreatitis. Experimental evidence shows that some starch compounds, particularly in the 100,000 to 300,000 D molecular weight range, have the advantage in sealing the capillary endothelium in case of increased permeability after ischemia or trauma, diminishing fluid and protein filtration and preventing edema.^{136,179,311,312}

In the resuscitation of hypovolemic shock (e.g., after trauma or burns), the use of hypertonic solutions with sodium concentrations greater than 0.9% also has gained wide interest.* The solutions essentially consist of hypertonic sodium chloride, to which colloids have often been added. The combinations include NaCl 7.5% with dextran 70 (6%/10%), NaCl 7.2% with dextran 60 (10%), and NaCl 7.5% with hydroxyethylstarch 6%.^{33,62,122,314-317} Hypertonic solutions usually result, at a much lower infusion volume than isotonic solutions (small volume resuscitation), in a rapid hemodynamic improvement, that is, an increase in cardiac output and in oxygen delivery and uptake and arterial blood pressure in experimental animals and patients with traumatic/hypovolemic shock.[†] Infusion of rapidly acting hypertonic saline, particularly if combined with hyperoncotic colloids, increases survival in bleeding animals compared with infusion of either component or other isotonic or hypertonic (nonelectrolyte) solutions.³¹⁶ Clinical trials also have shown some value of hypertonic solutions in the initial treatment of hypovolemic shock after burns and trauma with uncontrolled bleeding.^{119,286,314,316,317} The use of hypertonic saline solutions, however, warrants close monitoring of plasma sodium levels to prevent excessive hyponatremia and hyperosmolality.³¹³⁻³¹⁶

The hypertonic fluids primarily act through resorption of interstitial and cellular fluid volume and expansion of the plasma volume.^{7,131,314} It has been calculated that only 4 mL/kg 7.5% saline solution can increase circulating plasma volume by 8 to 12 mL/kg body weight. A hyperosmolality-induced increase in cardiac contractility may also contribute to the increase in cardiac output, although this effect has been doubted.³¹⁸ Other potential mechanisms include activation of pituitary and pulmonary osmoreceptors, leading to release of vasopressin and vagal afferent-mediated venoconstriction, and hyperosmolality-induced arterial vasodilation.^{7,62,313,314} Infusion of hypertonic sodium combined with hyperoncotic colloid solutions more rapidly and completely increases cardiac output and arterial blood pressure, and the effects last longer than those produced with infusion of hypertonic or colloid solutions alone.³¹³⁻³¹⁷ During infusion of hypertonic saline, particularly if combined with hyperoncotic colloid solutions, the

distribution of peripheral oxygen delivery is reversed to a more favorable pattern with preferential perfusion of vital organs, including gut and kidney.^{62,313} The increase in oxygen uptake in bled dogs was less rapid and complete during resuscitation with hypertonic saline plus hydroxyethylstarch, however, than during infusion of relatively large volumes of the latter.^{33,62}

The hypertonic solutions may also ameliorate immunodepression, the translocation of bacteria, and susceptibility to sepsis after hypovolemic shock in rodents.^{201,319} Hypertonic solutions (plus dextrans) restore capillary blood flow and organ function during resuscitation better than isotonic fluids because of their ability, among others, to reduce endothelial cell swelling, adhesion molecule expression, neutrophil activation and adherence, and cellular apoptosis compared with normotonic crystalloids such as racemic Ringer's lactate.^{191,320} Hypertonic solutions may also prevent lung injury after hemorrhage/resuscitation, probably via these mechanisms.^{95,119,122,319}

FLUID CONTROVERSIES

The choice between available fluids should be guided by the estimated extent and type of fluid losses; their composition and localization; and the properties of infusion fluids, their distribution over body compartments, and, perhaps, the associated costs, which are high for albumin, intermediate for artificial colloids, and low for crystalloid solutions.^{131,302-304} Nevertheless, the use of various solutions for resuscitation from hypovolemic shock is hotly debated, partly because the importance of the colloid osmotic pressure for resuscitation and prevention of pulmonary edema is uncertain.³⁰² Also, the relative merits and detriments (i.e., safety) of natural and artificial colloids remain unclear.^{302,321}

Capillary filtration depends on the pericapillary hydrostatic and the colloid osmotic pressure gradient, according to the Starling equation. If at a given permeability an imbalance in pressures augments capillary filtration of fluids, a decrease in interstitial colloid osmotic pressure, an increase in interstitial hydrostatic pressure (which also depends on the compliance of the interstitium), and increased lymph flow can either alone or in combination partially prevent gross accumulation of interstitial fluid (edema). The colloid osmotic pressure of plasma is primarily determined by the plasma albumin content and normally measures about 24 mm Hg.^{31,126,137,322} The pressure can be estimated from albumin and protein concentrations in plasma, but infusion of artificial colloid solutions invalidates this calculation, so proper assessment of plasma colloid osmotic pressure necessitates direct measurement.^{137,323} Because of a decrease in circulating plasma protein levels, hypovolemic shock results in a decrease in plasma colloid osmotic pressure.* During hypoproteinemia and a reduced plasma colloid osmotic pressure, fluid filtration for a given hydrostatic pressure increases until the pericapillary colloid osmotic pressure gradient decreases and a new steady state, often at increased lymph flow, has been achieved.^{133,135,136} Evoking safety mechanisms such as a reduced interstitial colloid osmotic pressure and increased lymph flow may keep the

*33, 62, 119, 122, 201, 210, 286, 292, 303, 313-317

†33, 62, 131, 210, 292, 313-317

*31, 126, 133, 134, 137, 182, 183

interstitium relatively dry, and these mechanisms may be more effective in the lung than in the systemic circulation.¹³³ During hypoproteinemia, the hydrostatic pressure needed to invoke pulmonary edema decreases, however, because of more rapid exhaustion of safety mechanisms.^{135,324} Conversely, increased lung water caused by an elevated hydrostatic pressure can be ameliorated by colloid infusion.³²⁴

For a given increase in hydrostatic pressure, the infusion of crystalloids decreases the plasma colloid osmotic pressure and tends to enhance, if insufficiently compensated by a decrease in the pericapillary colloid osmotic pressure gradient, pulmonary and systemic fluid filtration and interstitial fluid expansion more than infusion of albumin/colloids, which maintain plasma colloid osmotic pressure.* Crystalloid solutions replenish not only the intravascular but also the interstitial space by increased filtration, whereas colloid fluids tend to primarily fill the former compartment, at least initially.^{131,278} Widening of the intravascular-to-interstitial colloid osmotic pressure gradient may prevent increased fluid filtration, but the effect may be transient when some colloids have been filtered along with fluids into the interstitium and a new steady state of perimicrovascular pressure and draining lymph flow has been established.¹³⁶ The mechanism may form the basis for the well-known observation that colloid solutions yield a twofold to threefold greater expansion of the intravascular space than crystalloids and that the latter have greater tendency for edema formation for a given amount of fluid infused, so less colloid than crystalloid is probably needed for resuscitation to similar hemodynamic end points in hypovolemic shock.[†] In some clinical trials, colloids proved to be superior to crystalloids in resuscitation from hypovolemic shock,^{137,172,309} in terms of both the speed and the extent of correction of the hemodynamic abnormalities. Conversely, this may also explain the observations of some investigators that during resuscitation from hypovolemic shock pulmonary edema can be prevented in part if the intravascular filtration pressure (i.e., the gradient between plasma colloid osmotic and PCWP) is kept greater than approximately 6 mm Hg, with an elevated risk for pulmonary edema, particularly in case of increased permeability, if the gradient is less than approximately 3 mm Hg, and that resuscitation with colloids less often induces evidence for pulmonary edema than infusion of crystalloids during hypovolemic shock.[‡]

If the permeability for proteins increases and the reflection coefficient decreases, the hydraulic conductance of the capillary membrane also increases.¹³³ Increased permeability for proteins increases capillary fluid filtration for a given intravascular hydrostatic pressure and promotes the formation of edema.³⁰⁸ During increased permeability, the filtration of fluids and expansion of the interstitial fluid space depend more than normally on hydrostatic pressures and less on colloid osmotic pressures because the colloid osmotic pressure gradient is decreased.¹³³ The differences between the types of solutions in fluid filtration and formation of edema in the lung and peripheral tissues diminish.³²⁶ This may explain in part why some clinical studies did not find a predictive value of the colloid osmotic pressure-PCWP

gradient for pulmonary edema and lack of a difference between fluid types for formation of pulmonary edema and impaired gas exchange during resuscitation from hypovolemic shock.^{302,307} Moreover, an increase in CVP increases the back-pressure for lymph flow. Careful animal studies on hypovolemic shock combined with a lung vascular injury showed, however, that colloids are more effective than crystalloids in restoring the circulation and that the former increased lung water less than the latter unless permeability was severely increased.^{308,326} This can be explained by the fact that even in case of increased permeability the reflection coefficient is not zero, and that the pericapillary colloid pressure gradient still exerts some influence on the transcapillary movement of fluids.

Clinical studies on the colloid/crystalloid controversy may be difficult to interpret because of differences in patient populations and end points between fluid types.^{302,321} Lack of similar end points used for resuscitation may partly explain why infusion of colloid solutions increased the risk for pulmonary failure compared with infusion of crystalloids because colloids, owing to their greater intravascular volume-repleting effect, tend to increase hydrostatic filtration pressure in the lung more rapidly than crystalloid fluids even though colloid osmotic pressure is maintained or increases during infusion of the former and decreases with the latter.³⁰⁶ The importance of a difference in hydrostatic pressure for the risk of pulmonary edema would be accentuated in case of increased permeability.³⁰⁶ Finally, pulmonary mechanics, gas exchange, and radiographic changes used to evaluate the effects of fluid infusions in many studies may not accurately reflect changes in lung water.^{52,172,306-308}

There are safety concerns with artificial colloids, particularly in the presence of other risk factors for organ damage.^{304,321} Potential disadvantages of (artificial) colloid over crystalloid solutions include inhibition of the coagulation system; the risk for anaphylactoid reactions; inhibition of renal salt and water excretion; renal injury; and perhaps, at least for albumin, depression of myocardial function, possibly owing to binding of Ca^{2+} , although this has not been seen in all studies.^{171,172,321,327} Of all artificial colloids, dextrans affect coagulation most adversely, independently of hemodilution, by interfering with coagulation factors and diminishing thrombocyte and red blood cell aggregation.³²⁷ The gelatins may also have some intrinsic effects on coagulation, whereas the anticoagulant effects of hydroxyethyl starches probably relate, in addition to hemodilution, to less endothelial release of von Willebrand factor.^{290,311,327} Anaphylactoid reactions to artificial colloids are extremely rare and vary from slight fever and skin reactions to life-threatening anaphylactic shock. Starch compounds elicit these reactions less often than dextrans and gelatins.³¹¹ Large-molecular-weight starches may accumulate in subcutaneous tissues and may cause pruritus, even for weeks after administration.³¹¹ However, resuscitation of trauma patients with hydroxyethyl starch may result in less endothelial damage, renal injury, and pulmonary dysfunction than resuscitation with gelatins.¹⁷⁹ Nevertheless, the renal damaging effect of starch is probably greater than that of gelatins in patients with prior risk factors for acute kidney injury.³²¹ Hence, colloids may contribute to the development of acute kidney injury and failure, particularly in the case of

*31, 126, 133–137, 172, 183, 303, 307, 324

†25, 135, 137, 172, 307–309, 325

‡31, 134, 137, 172, 303, 308, 309, 322, 323

overadministration, which may otherwise be more frequent with artificial colloids than with albumin/plasma solutions, which can be monitored by measurements of plasma albumin concentrations. As opposed to albumin/plasma, infusion of colloid solutions is often bound to a maximum (see Table 26.5). Side effects may be more frequent with artificial colloids than with albumin/plasma infusion even though the latter carries a very low risk of anaphylactoid reactions and disease transmission. Crystalloid and artificial colloid solutions may activate neutrophil-endothelial interactions and depress macrophage and immune functions more than albumin does.^{191,321,328,329} In contrast to lactated Ringer's solution, Ringer's ethyl pyruvate solution has favorable anti-inflammatory and cell-protecting actions.^{29,37}

If used in the resuscitation from hypovolemic shock, artificial colloids may still be preferred over natural colloids because the latter are more expensive and less available, even though albumin and plasma solutions are effective volume expanders. There is some evidence that the type of fluids infused during hypovolemia may influence the extent and speed with which oxygen uptake is restored: infusion of colloid (plasma/albumin) solutions in hypovolemic postoperative and trauma patients may increase uptake of oxygen for a given increment in plasma volume and oxygen delivery more rapidly than infusion of crystalloids and may thereby improve outcomes.^{9,25,330} This is thought to result in part from increased diffusion distances for oxygen in the tissues subsequent to tissue edema, evoked by massive crystalloid infusion.^{9,25,307} Administration of non-buffered (unbalanced) crystalloid solutions such as normal saline carries the risk of hyperchloremic metabolic acidosis, which can be avoided in part by infusion of buffered (balanced) solutions such as Ringer's lactate.³²⁵ Nevertheless, meta-analyses suggest, at least in some groups, a slightly increased mortality risk after resuscitation with artificial colloids.^{302,321,331,332} In the SAFE study comparing albumin and saline for resuscitation in the intensive care unit, a slight but nonsignificant increase in mortality rate was observed in the (neuro)trauma subgroup treated by albumin infusions, although animal studies suggest some beneficial and anti-inflammatory effects of albumin resuscitation from hemorrhagic shock.³³³

BLOOD PRODUCTS AND SUBSTITUTES

Resuscitation with blood components may restore tissue oxygen delivery and energy metabolism more rapidly, completely, and persistently than resuscitation with crystalloid during hemorrhage and hypovolemic shock, although this is controversial.^{162,305} Nevertheless, it has been suggested that infusion of sodium salts may be essential, and that addition of saline to blood improves survival from hypovolemic shock after hemorrhage because of correction of both the intravascular and the interstitial volume deficits.³¹³

In the treatment of hypovolemic shock following ongoing hemorrhage, infusion of red blood cells in the form of erythrocyte concentrates, or packed red blood cells, remains crucial.^{277,286,334} This is achieved by autotransfusion from uncontaminated areas during surgery, if possible; by infusion of blood group O Rh-negative donor blood in emergency situations; or by infusion of typed and stored/anticoagulated donor blood. The position of the

oxyhemoglobin dissociation curve of old, stored blood is shifted to the left.^{60,78} Although this theoretically may impair the delivery and uptake of oxygen in the tissues, the effects of these changes in animal experiments are usually limited and clinical repercussions are unclear.^{60,76} Transfusion of substantial amounts of erythrocyte concentrates is preferentially accomplished through a microfilter to avoid alloimmunization and infusion of neutrophils and other cellular aggregates, which develop in time during storage of blood and which may lodge in the lung, promote pulmonary injury, and impair gas exchange, leading to TRALI.¹⁷⁵⁻¹⁷⁷ Today, prior leukocyte-reduced red blood cell concentrates are often used, but it is controversial whether this is associated with less risk. Excluding multiparous women who may have become sensitized to allogenic leukocytes and may carry leukocyte antibodies contributing to TRALI is another strategy applied in some countries. Also, humoral mediators released in stored blood or during infusion might be responsible in part for pulmonary vascular injury after massive transfusion of blood.^{180,190} Nevertheless, massive transfusion may remain a risk factor for bacterial sepsis, ARDS, and MOF, independently from bleeding and severity of hypovolemic shock.* Finally, transfusion of blood components and plasma carries a small risk of transmitting infectious diseases and depressing immune function.^{305,329}

Because loss of blood also leads to loss of coagulation factors and platelets, and blood concentrations are diluted further during nonsanguineous fluid resuscitation, replenishing plasma levels by infusion of fresh frozen plasma and platelets is usually required to help stop ongoing bleeding.²⁶² Fresh frozen plasma should not be used solely for the treatment of hypovolemia, even though plasma may diminish endothelial hyperpermeability through restoration of glycocalyx.^{262,271} The strategy of blood products infusion has undergone some changes in the last decade, in which studies suggest optimal hemostasis and outcome when fresh frozen plasma units are infused at a 1:1 ratio with packed red blood cell concentrates and random donor platelet units at a 1:3 to 1:5 ratio.^{334,337,338} If, during resuscitation, the clotting times are prolonged by a factor of 1.5 or more, more fresh frozen plasma can be given, and if platelet counts decrease to less than 50 to 100 $\times 10^9/L$, platelets can be transfused, particularly in case of intracranial or life-threatening bleeding. The value of prophylactic administration of coagulation factors in a polytransfused, traumatized patient to prevent further bleeding after initial hemostasis is unclear, however. Supplementation of Ca^{2+} may be necessary only if more than 12 to 20 units of packed red blood cells, anticoagulated with Ca^{2+} -binding citrate, have been given if rapidly transfused and particularly if liver function is impaired.¹⁵⁰ Further treatment is guided by ionized Ca^{2+} determinations in plasma. Fibrinogen concentrates are increasingly used with increasing evidence that fibrinogen plays an important role in coagulation and that primary hyperfibrinolysis is common in trauma patients, as revealed by thrombelastometry.^{334,337} Antifibrinolytic drugs, such as tranexaminic acid, given prior to fibrinogen concentrates are useful adjuncts.³³⁹ The exact place of recombinant factor VIIa, a potent procoagulant, in the treatment of refractory bleeding has not been settled yet.^{286,340} The factor stops

*84, 175–177, 180, 181, 190, 335, 336

bleeding and saves blood transfusion, but cost-effectiveness is unclear. Adverse effects include a tendency for thromboembolic events.³⁴⁰ The bleeding tendency of trauma is also aggravated by hypothermia and acidosis, but it is unclear whether aggressive treatment of hypothermia or acidosis substantially ameliorates coagulation disturbances and to what extent DIC contributes.^{181,264,337} The importance of the latter also remains somewhat unclear, and treatment may consist of infusion of antithrombin III concentrates or, in case of severe bleeding, of fresh frozen plasma and platelets.¹⁸¹

To overcome some of the problems associated with donor or autologous red blood cell transfusions, investigators have intensively searched for safe and effective hemoglobin substitutes applicable in humans.^{230,286,341-343} These substitutes include chemical oxygen carriers, hemoglobin modifications, and liposome/vesicle-encapsulated hemoglobin.³⁴⁴ The chemical hemoglobin modifications have been designed to prevent or limit the renal toxicity of free hemoglobin. They include polymerized, modified, cross-linked, and recombinant hemoglobins.^{34,345} The use of hemoglobin substitutes has been under clinical investigation. Some non-recombinant substitutes seemed to increase arterial and, particularly, pulmonary arterial blood pressure more than accounted for by fluid loading, but some compounds have more adverse effects than others.³⁴⁶ This may relate to the property of hemoglobin to scavenge NO or release endothelin and platelet-activating factor, or combinations, and the use of these solutions is therefore still not without hazard.³⁴⁶ Diaspirin cross-linked hemoglobin may beneficially influence intracranial hemodynamics during resuscitation from hypovolemic shock.²⁹⁶ A clinical trial on diaspirin-cross-linked hemoglobin in trauma failed to improve survival over resuscitation with saline, however.³⁴¹ The use of hemoglobin substitutes such as perfluorocarbons has not yet reached the stage of widespread, routine clinical practice, although they may effectively carry oxygen in humans and may improve resuscitability from hypovolemic shock following bleeding in animals compared with nonhemoglobin-based solutions.^{341-343,347} Further research is ongoing.

ACIDOSIS AND OPTIMAL HEMATOCRIT

The underlying idea for partial correction of metabolic acidosis is that acidosis is detrimental for, among others, myocardial function by increasing pulmonary artery pressure and right ventricular afterload, impairing catecholamine sensitivity, and diminishing adrenergic receptors and intracellular Ca^{2+} transport necessary for contraction, even if masked by increased sympathetic activity.^{36,168} Metabolic acidosis may increase the tendency for life-threatening ventricular arrhythmias and may lessen defibrillation thresholds and vascular tone.²⁷ The need for treatment of metabolic (lactic) acidosis (e.g., by intravenous administration of buffer solutions) remains unclear.* Administration of sodium bicarbonate may carry the risk for aggravation of intracellular acidosis in the tissues because bicarbonate releases CO_2 during buffering and CO_2 more rapidly

traverses the cell membrane than the bicarbonate ion.* Alkali therapy with sodium bicarbonate carries the risks of shifting the oxyhemoglobin dissociation curve to the left and impairing tissue oxygenation, a decrease in ionized Ca^{2+} , and causing hypernatremia and osmolarity, although the consequences of these theoretical drawbacks are unclear.^{27,36,44} Albeit not beyond doubt, experimental and clinical studies suggest that the administration of buffers such as sodium bicarbonate is not harmful, even though the hemodynamic and metabolic effects of the solution may not surpass those obtained by saline infusion.[†] In many institutions, small doses of alkali buffers such as sodium bicarbonate (50 to 100 mL of a 4.2%, 0.5 mmol/mL solution) are still given to treat metabolic (lactic) acidosis if arterial pH is less than 7.2 and acidosis persists despite optimal cardiovascular resuscitation.^{27,36} During sodium bicarbonate infusion, the patient should be hyperventilated to prevent hypercapnia in arterial blood and bicarbonate doses should be guided by the arterial blood acid-base status to prevent alkalosis and diminished oxygen release after overadministration.^{27,44,348} Prevention of hypercapnia may obviate increased CO_2 diffusion and aggravation of intracellular acidosis.^{27,36} The value of buffers, including bicarbonate/carbonate, that do not generate CO_2 and prevent aggravation of intracellular acidosis is still controversial.^{27,35,348,349} Dichloroacetate is a stimulator of pyruvate dehydrogenase, and the drug may ameliorate lactate accumulation and postresuscitation organ dysfunction, but there is probably no benefit for patient outcome.^{27,35,36}

The hematocrit is the main determinant of blood viscosity, and the latter determines, together with the geometric features of the vascular bed, the blood flow in the microvasculature.¹²⁰ Experimental studies suggest that during normovolemic hemodilution normal oxygen delivery is achieved at a range of hematocrit values from 12% to 65% for the heart; 30% to 65% for the brain; 30% to 55% for liver, intestine, and kidney; and 30% to 60% for the whole body because adaptations in vessel diameter and changes in blood flow in this hematocrit range are able to compensate for changes in oxygen content, maintaining a normal oxygen delivery.^{85,120,265,350} The optimal hematocrit for the whole body may not conform to the regional optimal hematocrit.

Because blood is a non-newtonian fluid, so that blood viscosity depends not only on hematocrit but also on blood flow velocity (shear stress), there may be differences along the vascular profile in blood viscosity, with propensity for red blood cell aggregation in postcapillary venules, where flow velocity is lower than in arterioles, particularly during hypovolemic shock.^{4,120} Increased blood viscosity in postcapillary venules may contribute to impaired tissue perfusion during hypovolemic shock.⁴ Conversely, the volume status, myocardial function, and vascular tone contribute to blood viscosity so that, for example, the optimal hematocrit for oxygen delivery is lower during hypovolemia than hypervolemia.^{21,120,350} Finally, red blood cell deformability is decreased in hemorrhagic shock, contributing to increased viscosity.²²⁴

*27, 35, 36, 44, 52, 348, 349

*27, 35, 36, 52, 348, 349

†27, 35, 36, 44, 348, 349

Taken together, it is hard to generally define the optimal hematocrit for oxygen delivery to the body during hypovolemic shock, even though hematocrit-induced changes in the rheologic properties of blood may contribute to hemodynamic changes in critically ill patients.^{21,120,350,351} Most, but not all, authors believe, however, that mild hemodilution (hematocrit approximately 0.30) may benefit delivery and uptake of oxygen in the tissues and promote survival of critically ill patients with hypovolemia, whereas severe hemodilution or hemoconcentration may be detrimental.* A low hematocrit in the course of hypovolemic shock after major surgery may warrant red blood cell replacement, whereas a high hematocrit may necessitate infusion of non-sanguineous fluids.^{9,352} Mild hemodilution may benefit resumption of red blood cell flow and oxygen uptake after prior ischemia.

VASOACTIVE DRUGS

Generally, catecholamines do not have a place in the treatment of hypovolemic shock unless they are used to bridge a period in which infusion fluids are not yet available, or if adequate fluid resuscitation has proved insufficient to reverse hypotension (irreversible shock) and to increase oxygen delivery to the point that tissue needs are met.[†] Persistent hypotension despite normovolemia can be caused by a low cardiac output following myocardial dysfunction or by peripheral vasodilation. Data obtained with advanced hemodynamic monitoring may help to identify these abnormalities, which can be important for choosing among the available vasopressor and inotropic drugs, which have widely differing receptor affinities and hemodynamic effects.^{9,45}

Treatment with the drugs is best guided by the prevailing hemodynamic profile and aims at optimization of the circulation toward values associated with survival.^{9,42,45} Drugs are given as a continuous intravenous infusion, preferably via a central vein. The initial dose is low, and often combinations of drugs are used. The use of catecholamines should be judicious and carefully guided by hemodynamic parameters to reach predefined hemodynamic goals.⁹ β -Adrenergic drugs increase cardiac output by inotropic (β_1) or vasodilating (β_2) properties.^{9,353} Dopaminergic compounds may preferentially increase splanchnic and renal perfusion, glomerular filtration, and diuresis.^{66,284} Dobutamine, having vasodilating β_2 properties, may exert greater effects on delivery and uptake of oxygen than dopamine at a lower PCWP.^{9,353} A decrease in the arterial blood pressure concomitantly with a decreased wedge pressure after dobutamine infusion may warrant additional fluid repletion.⁹ Drugs with α -adrenergic activity, such as norepinephrine, increase arterial blood pressure, but this increase may not lead to a decrease in cardiac output because they may increase venous return to the heart by decreasing venous compliance.⁷ The vascular reactivity to vasoconstrictors may diminish in the late phase of shock, but norepinephrine remains the agent of first choice in the (bridging to definitive) treatment of hypovolemic shock after fluid loading.³⁵⁴ The use of adrenergic drugs is not without hazards. They

may enhance the metabolic demands of the body so that the oxygen supply-to-demand ratio is not favorably influenced even if oxygen delivery is enhanced.³⁵⁵ Particularly, epinephrine may increase lactic acid levels independently of oxygen balance.³⁸ Low-dose dopamine has been shown, at least in bled dogs, to impede oxygen extraction by the gut during a decrease in oxygen supply, probably associated with transmural distribution of blood flow.⁶⁶ Finally, vasoconstricting vasopressin and methylene blue, a guanylate cyclase inhibitor, have been tried to overcome intractable hypotension in this phase.^{96,300} Vasopressin has also been used in the initial management of uncontrolled hemorrhagic shock to safeguard arterial pressure for vital organ (e.g., cerebral) perfusion without overzealous fluid administration that may dilute coagulation factors and promote further bleeding.³⁰⁰

BRAIN INJURY AND RESUSCITATION

Hypovolemia and a decreased mean arterial blood pressure are considered as major threats for cerebral perfusion in brain injury. The latter may create intracranial hypertension following edema, bleeding, and contusion so that perfusion is more dependent on pressure than normal. Small volume resuscitation from hypovolemia with hypertonic (and hyperoncotic) solutions could increase mean arterial blood pressure at a small increase in plasma volume and could, by virtue of hypertonicity, decrease cerebral edema and intracranial pressure. The solutions are highly suitable for treatment of multiple trauma that includes the brain.^{314,315} Conversely, too much normotonic, certainly hypotonic, and perhaps albumin solutions may aggravate cerebral edema, but too little fluids and under-resuscitation with resulting hypotension and hypoperfusion may do the same. Vasopressor drugs such as vasopressin may be useful adjuncts in the initial treatment of hemorrhagic hypotension plus brain injury.

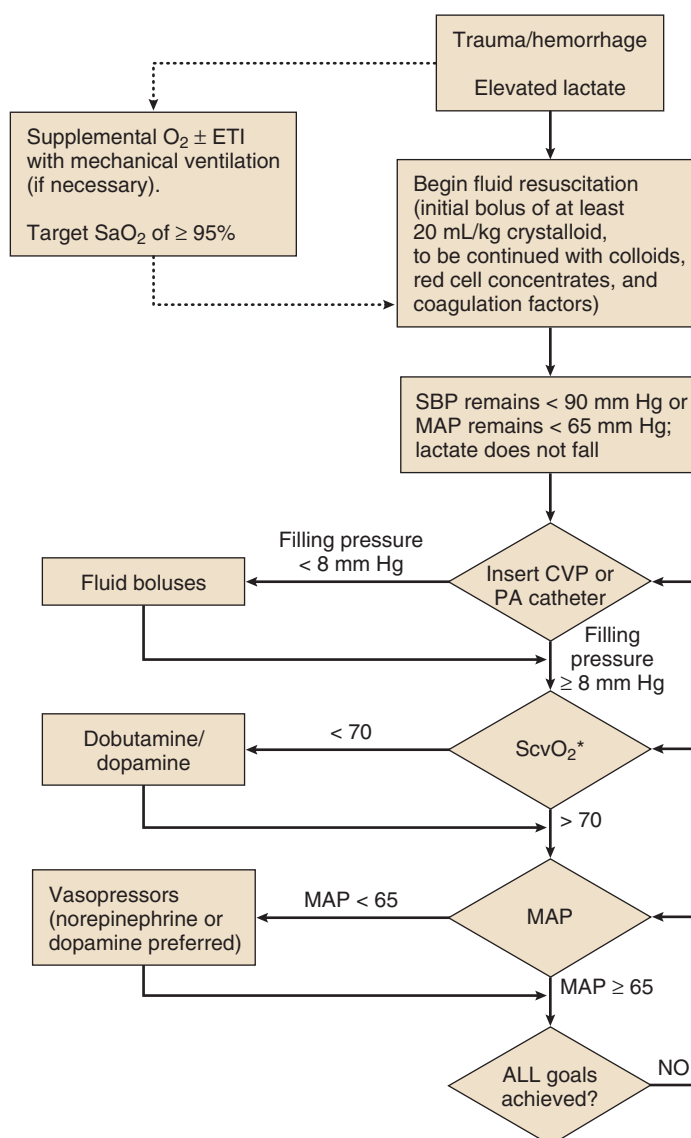

IN PRACTICE

In practice, the different types of fluids, including isotonic and hypertonic crystalloid and iso-oncotic or hyperoncotic colloid solutions, are often combined in the resuscitation from hypovolemic shock (see [Box 26.2](#)). For resuscitation of hypovolemic shock following hemorrhage, typed blood is often not immediately available, even though a blood sample for crossmatching has been sent to the blood bank as soon as possible after admission. If shock is severe and warrants immediate infusion of blood, type O Rh-negative erythrocyte concentrates can be safely used. In the absence of blood, resuscitation should begin with nonsanguineous fluids. During hypovolemic shock, initial resuscitation is often begun with hypertonic or isotonic (balanced) crystalloids, supplemented with colloid solutions, and finally accomplished through infusion of erythrocyte concentrates and plasma ([Fig. 26.2](#)).

In the case of uncontrolled diabetes mellitus, profound diarrhea, and acute adrenocortical insufficiency with loss of plasma water and electrolytes, the infusion of crystalloid solutions usually suffices. These solutions restore intravascular, interstitial, and intracellular (in case of diabetes

mellitus) fluids. Changes in the electrolyte concentrations in blood have to be corrected through adaptation of the type and composition of the infusion fluid; in the case of hypokalemia (and in the presence of diuresis), potassium should be supplemented.

SUPPORTIVE CARE

A vomiting patient in hypovolemic shock should be protected against aspiration of gastric contents by early intubation. The value of specific measures for prevention of hemorrhagic gastric mucosal stress ulceration remains controversial.²⁰⁷ After resuscitation from shock, attention also should be paid to the nutritional status of the patient.²²² It should be judged whether enteral or parenteral nutrition is

necessary to improve nitrogen balance and energy intake.³⁵⁶ Although enteral feeding during hypovolemic shock and after resuscitation may increase metabolic demands of the gut, luminal application of nutrients such as glutamine may induce an increase in mucosal blood flow, ameliorate damage, and diminish the likelihood for translocation of endotoxins and bacteria and of septic complications.^{148,206} In addition, there is some evidence that early enteral feeding favorably influences organ function after hemorrhage and reperfusion, in contrast to (early) parenteral feeding, which may have adverse effects even though earlier meeting caloric requirements.¹⁴⁸ The value of selective decontamination of the digestive tract or luminal absorption of endotoxin to prevent sepsis and its harmful sequelae originating from the gut is still controversial in multiple trauma, although such

measures may inhibit the cytokine response to hypovolemic shock in animals.³⁵⁷

When treating pain in a patient with extensive trauma, morphinomimetics are cautiously applied because the drugs may have adverse circulatory effects during hypovolemic shock and half-life may be prolonged.^{11,358} Because many resuscitated patients after trauma or hemorrhage exhibit hypothermia, partly caused by exhausted energy reserves and infusion of substantial amounts of room temperature infusion fluids, and because hypothermia may denote more severe illness, rewarming infusion fluids may be necessary during resuscitation, and this may prevent some organ dysfunction and perhaps promote survival despite the increase in oxygen demand with an elevation in body temperature.^{56,217,264} In contrast, there also may exist some protective effect of mild hypothermia during bleeding and resuscitation, particularly when accompanied by brain injury, at least in experiments.

MISCELLANEOUS THERAPIES

A wide array of experimental drugs has been tried in animal experiments to improve the hemodynamics, ameliorate inflammation, and increase survival rates from hypovolemic shock and resuscitation.²³⁰ Although many experimental drugs have shown some benefit in animal models of hypovolemic shock, in terms of hemodynamics during shock and after resuscitation and ultimate survival, there are now clinical trials ongoing or showing a benefit of such interventions in humans, including treatment with immune-enhancing factors.^{24,93,118,230,359} Blockers of NO synthesis (L-arginine analogs) and NO donors, inhibitors of activated K⁺ channels (oral antidiabetic, sulfonylurea drugs), Na⁺/H⁺ exchanger (amiloride, benzamide), and poly(ADP-ribose) polymerase have been tried in animal experiments to overcome vascular unresponsiveness, inflammation, and organ dysfunction early or late after development of hypovolemic shock.* ATP-MgCl₂ may provide energy to cells, improve the microcirculation, reduce cell swelling, protect tissues from injury, and promote organ function and survival during hypovolemic shock and resuscitation.^{24,128,143,144} Ca²⁺-entry blockers have been used to prevent intracellular accumulation of Ca²⁺ and further damage of ischemic cells during resuscitation from hypovolemic shock.[†] Opiate antagonists or inhibitors such as naloxone, ACTH, and thyrotropin-releasing hormone been shown to increase arterial blood pressure, decrease inflammation, and improve survival.[‡] Sedatives and analgesic drugs such as dexmedetomidine and ketamine may have anti-inflammatory properties and are tissue protective.³⁶⁰ Other vasoactive agents, including thyroid hormone, glucagon, and angiotensin inhibitors, with a preferential effect on splanchnic blood flow also may have beneficial effects in hypovolemic shock.^{105,225,226}

Experimental models indicate that pretreatment with xanthine oxidase inhibitors (allopurinol) or scavengers of ROS or antioxidants including lazaroids may ameliorate microvascular hemodynamics and membrane injury of

organs such as the heart and gut and improve survival after resuscitation from hypovolemic shock, although some of these compounds may have greater effects than others.* A study in trauma patients with elevated lipid peroxidation products in plasma showed that superoxide dismutase ameliorated the inflammatory response and MOF.²³⁹ It has been suggested that corticosteroids prevent lysosomal disruption and release of toxic proteases, prevent NO synthesis, and ameliorate the hemodynamic changes and promote survival during hypovolemic shock in animals.^{92,167,229,268} Cortisol treatment may increase the vascular sensitivity for catecholamines, particularly in patients in whom adrenal cortisol secretion is low relative to severity of disease, the so-called relative adrenal insufficiency. It may also decrease respiratory infections in the hospital course.³⁶¹ Intravenously administered ACTH fragments may have an adrenal-independent central opioid-inhibiting effect, which may help to prevent vascular decompensation and treat hypotension, even clinically.⁹³ Drugs such as pentoxifylline and complement inhibitors may prevent neutrophil-mediated endothelial injury, dysfunction, and downregulation of NO synthesis after bleeding and resuscitation, diminishing endothelium-dependent vasodilation.^{118,215} Pentoxifylline may ameliorate not only macrophage cytokine generation, but also adhesion molecule expression and neutrophil activation and aggregation and may improve red blood cell deformability. Administration of pentoxifylline or other methylxanthines may ameliorate reperfusion injury, at least in the rat gut and liver, and survival may be enhanced.^{79,166,206,230,319}

Heparin and nonanticoagulant heparin sulfate or other analogues may have anti-inflammatory effects and may improve the microcirculation, and administration may partly protect various tissues, including the liver and gut, against reperfusion injury after hypovolemic shock by bleeding.^{250,363} Protease inhibitors, such as aprotinin, may also have beneficial effects. Administration of female hormones or inducers such as dehydroepiandrosterone or testosterone depletion after trauma/hemorrhage and resuscitation partly protects animals from microcirculatory organ dysfunction and immunosuppression, and a wide variety of mechanisms has been implicated.²¹⁸ The potential of other immunologic and hormonal agents to treat immunosuppression has also been shown.^{218,250,362} Further drug developments include anticytokine strategies and tissue protective agents interfering with cell stress, apoptosis, or necrosis, such as erythropoietin.²¹⁶ Mesenchymal stem cells are under investigation.

COMPLICATIONS AND PROGNOSIS

As previously indicated, hypovolemic shock may adversely affect the function of various organs. Even after successful resuscitation from hypovolemic shock, some patients may develop dysfunction of various organ systems (MOF), as evidenced by ARDS, acute kidney injury and failure, hyperbilirubinemia, diminished motility and resorptive capacity of the bowel, ischemic colitis, anoxic brain damage, severe

*92, 93, 139, 147, 221, 230

*194, 198, 199, 227, 228, 230

muscle loss, and complications such as acalculous cholecystitis, ischemic perforation of the bowel, and DIC with a bleeding tendency.* The pathogenesis of the syndrome in humans is still unclear and probably multifactorial, so poly-transfusions, ischemia, reperfusion injury, inflammatory reactions, and metabolic changes all may play a role, as previously mentioned.^{180,190,228} Hemorrhagic (hypovolemic) shock after trauma may be complicated on days 1 to 3 after the trauma by the systemic fat embolism syndrome, with low platelets and petechiae, fever, acute lung and brain injury, and retinal abnormalities. Prevention and treatment of such complications involves stabilizing fractures, preventing intramedullary pressure, and otherwise being merely supportive. Therapy of the MOF syndrome is also supportive and aimed at the replacement of organ function, prevention and treatment of infections, adequate nutrition, and circulatory support.²²² During development of ARDS, the disturbed gas exchange does not respond to liberal oxygen therapy, so intubation and mechanical ventilation are often required for oxygen delivery to the tissues. Further treatment is aimed at diminishing pulmonary edema by judicious manipulation of the hydrostatic pressure in the lungs and the colloid osmotic pressure of plasma (e.g., with help of diuretics), avoiding a decrease in oxygen transport to the tissue. In the case of acute kidney injury and failure, attempts can be made to treat fluid overloading by promoting diuresis with help of diuretics if arterial blood pressure is adequate. If unsuccessful, renal replacement therapy (e.g., by continuous arteriovenous or venovenous hemofiltration) may be necessary.³⁶⁵ There is also some suggestion that the technique, when large ultrafiltration fluid volumes are used, allows for some removal of harmful proinflammatory mediators from the circulation and contributes to hemodynamic stabilization and organ function independently of renal replacement therapy.³⁶⁵

As mentioned, hemorrhage, shock, and resuscitation after trauma may transiently alter immune responses. Together with wounds, this may predispose to susceptibility for bacterial infection and sepsis. Sepsis is a common complication of trauma and is believed to contribute to the development of MOF, including ARDS, in patients ultimately dying.^{2,205} Because trauma itself may result in fever and leukocytosis, the recognition of bacterial infection and sepsis in trauma patients is difficult; recognition is aided by infection markers such as circulating C-reactive protein and procalcitonin. Suspected or proven infection should be treated by appropriate antibiotics and drainage, if needed. Despite cardiovascular supportive measures, MOF carries a mortality rate approaching 100% if more than three to four systems fail.^{82,205,270}

CONCLUSION

Hypovolemic shock is a life-threatening condition necessitating prompt diagnosis and therapy to prevent MOF and death. Despite new insights into pathophysiology and new horizons for treatment, the main principles of management remain the rapid and complete repletion of circulating blood volume and treatment of the underlying cause.

*2, 40, 82, 205, 239, 263, 364

KEY POINTS

- Hypovolemic shock is an acute disturbance in the circulation leading to an imbalance between oxygen supply and demand in the tissues caused by a decline in circulating blood volume.
- Changes in the blood lactate or bicarbonate level reflect the severity and course of shock and roughly predict outcome.
- Compensatory mechanisms evoked during hypovolemic shock attempt to defend vital organ perfusion and function.
- Hypovolemic shock leading to ischemia-reperfusion triggers an inflammatory response. The syndrome also is characterized by a diminished immunologic defense.
- The most frequent cause of hypovolemic shock is trauma.
- The main principles for treatment of hypovolemic shock are rapid and complete repletion of circulating blood volume and treatment of the underlying cause. In principle, vasoactive drugs have no place in the treatment of hypovolemic shock.
- Advanced hemodynamic monitoring is indicated in case of difficulties in diagnosis, treatment of hypovolemic shock, or both.
- During treatment of hypovolemic shock, repletion of circulating blood volume and oxygen delivery to the tissues is more rapid with infusion of colloid than of crystalloid fluids unless the latter are hypertonic. On the other hand, synthetic colloids have more (severe) adverse effects and their safety is currently hotly debated. Infusion of concentrates of red blood cells and fresh frozen plasma is indicated in the case of blood loss.
- The pathogenesis of MOF after hypovolemic shock is multifactorial. The main preventive measure is a rapid restoration of tissue oxygen balance.

In 1934, Blalock suggested four categories of shock: hypovolemic, vasogenic, neurogenic, and cardiogenic.^{1,2} In more recent clinical practice, additional categories of shock have been proposed.³ Hypovolemic shock, the most common, results from reduction in circulating blood volume. Volume loss may be loss of whole blood, plasma, or extracellular fluid or a combination of all three. Vasogenic shock occurs as a result of changes in the resistance of vessels so that a normal blood volume fails to occupy the available space. Neurogenic shock (spinal shock) is a form of vasogenic shock in which spinal anesthesia or spinal cord injury leads to vasodilation. Septic shock is another form of vasogenic shock in which there is increased capacitance. A decrease in peripheral arterial resistance, a decrease in venous capacitance, and a peripheral arteriovenous maldistribution occur. Cardiogenic shock results from failure of the heart as a pump. Obstructive shock results from mechanical obstruction to cardiac function, as seen with tamponade, tension pneumothorax, or massive pulmonary embolism.⁴

Traumatic shock includes several components of the conditions mentioned previously.⁵ Hypovolemia caused by blood loss is compounded by neurogenic, cardiogenic, or obstructive shock plus the vasogenic component of maladaptive mediator cascades initiated by tissue injury. Traumatic shock involves hemorrhage in combination with soft tissue trauma and fractures. As a result, study of pure hemorrhagic shock may have limited relevance to the pathophysiologic condition of traumatic shock. Most studies have shown significant differences in the biologic condition of traumatic shock compared with that of pure hemorrhagic shock based on the activation of mediator cascades.²

Conflicting observations in literature are due at least in part to the assumption that hemorrhagic shock and traumatic shock are identical insults.^{2,3} Pulmonary complications after simple hemorrhage are uncommon in clinical practice, but pulmonary dysfunction is a common comorbid condition after major trauma with attendant soft tissue or long bone injury.^{2,6} Activation of mediator systems is far

more intense with traumatic shock than with pure hemorrhage.⁷ Conflicting data regarding changes in cytokine levels after a traumatic insult are likely due to the fact that systemic cytokine levels do not reflect local production of these mediators. Measurement of tissue levels of mediator production may be necessary to determine accurately whether there is upregulation of various mediator systems after trauma or hemorrhage.

Soft tissue injury alone upregulates mediator systems.^{2,8} A small animal study with closed femur fractures showed Kupffer cell activation 30 minutes after injury.⁹ Another study assessed the effects of skeletal muscle injury in combination with hemorrhage in a porcine model of hemorrhagic shock. To reach a given physiologic end point (reduction in cardiac index and oxygen delivery), hemorrhage of 40% of the blood volume was required in a pure hemorrhagic shock model. If skeletal muscle injury was added, hemorrhage of only 29% of blood volume was necessary to reach the same end point.^{2,10} The ability to maintain cardiac function after hemorrhage was impaired in this study by superimposition of a soft tissue injury, emphasizing the difference between hemorrhagic shock and traumatic shock. A synergy in activation of neuroendocrine and inflammatory mediator systems is likely when traumatic injury and hemorrhagic shock are present. More recent work describing coagulation changes occurring with injury emphasizes the danger of combined injury and hypoperfusion of soft tissue in failure of appropriate coagulation response.¹¹

CLASSIC NEUROENDOCRINE RESPONSE

The essential homeostatic response to acute blood loss is preservation of cerebral and cardiac perfusion with maintenance of normal blood pressure as sensed by carotid body and aortic arch receptors. Peripheral vasoconstriction and curtailment of fluid excretion are seen. Cardiac contractility and peripheral vascular tone also are altered. Pain, hypoxemia, acidosis, infection, changes in temperature, and availability of substrates such as glucose affect this response. A decrease in blood volume alone without hypotension may activate the hypothalamic-pituitary axis. The magnitude of neuroendocrine response depends not only on the volume of blood loss, but also the rate at which blood loss occurs. This response may be modified by patient age, prescribed medications, preexisting illness, and the use of ethanol or other drugs. With spinal cord transection, operative intervention below the level of injury does not produce typical activation of the hypothalamic-pituitary axis. Similarly, consciousness is unnecessary for activation of this response because it may occur under anesthesia.^{2,12-16}

The initial effect seen with hemorrhage is sympathetic vasoconstriction. Capacitance of the circulatory system is reduced, and aortic arch or carotid sinus baroreceptors respond to changes in blood pressure by modulation of sympathetic tone.^{2,17} Atrial receptors respond to changes in vascular wall stretch and pressure. Afferent vagal fibers carry signals leading to loss of tonic inhibition of heart rate and immediate activation of thoracolumbar sympathetic outflow with norepinephrine release from postganglionic

sympathetic fibers. As blood loss increases, so does the role played by arterial baroreceptors. Another part of this hormonal response is corticotropin-releasing factor secreted by the hypothalamus, vasopressin release, and growth hormone-releasing factor release.¹²

The clinician sees cool extremities in response to these changes associated with hypovolemia. Venous capacitance also decreases, resulting in accelerated venous return to the heart. Selective arterial vasoconstriction maintains blood flow to the heart and brain until compensation fails. Intense triggering of sympathetic signals is activated when arterial blood pressure decreases to less than 50 mm Hg and is maximally stimulated when systolic blood pressure is less than 15 mm Hg.² Although metabolic vasoregulation in the heart and brain helps avoid local vasoconstriction, blood flow to other tissues decreases dramatically. Renal blood flow may be reduced to 5% to 10% of normal with acute hypovolemia. Flow to the splanchnic circulation, skin, and skeletal muscle also decreases. These vasoconstrictor responses are mediated by epinephrine and norepinephrine from the adrenal medulla and local sympathetic activity at the vasculature. With increases in acidosis and hydrogen ion concentration, coronary vasodilation occurs as opposed to constriction of arteries in skeletal muscle and the splanchnic circulation.^{3,18,19}

Multiple endocrine responses are seen with trauma and associated hypovolemia. Plasma levels of glucagon, growth hormone, cortisol, and corticotropin (adrenocorticotropic hormone) increase.^{2,3,5} The renin-angiotensin-aldosterone axis is stimulated with release of vasoconstrictive angiotensin II. Vasopressin release also occurs after hemorrhage, resulting in water absorption in the distal tubule of the kidney. Vasopressin induces splanchnic vasoconstriction. Research suggests that with prolonged hemorrhage, vasopressin depletion may occur, and supplements of this hormone by clinicians may be warranted. Growth hormone and glucagon promote gluconeogenesis, lipolysis, and glycogenolysis. Catecholamines that inhibit insulin release and hyperglycemia and increase blood osmolarity are thought to shift fluid from cells and the interstitium into the intravascular space. More recent data associate hyperglycemia in the setting of injury with adverse outcome, however. The cellular mechanism for this response remains unclear. Loss of fluid or salt through the kidneys also is limited by these hormonal effects, which serve to conserve the circulating blood volume.^{18,20-22}

Compensated acute hypovolemia occurs when the aforementioned mechanisms are sufficient to avoid widespread cellular injury and organ decompensation.² If volume loss continues, or resuscitation is inadequate, a cycle of decline occurs with regional perfusion defects leading to tissue and microcirculatory changes. Progression from compensated to decompensated and irreversible shock is often defined in retrospect. Frequently, a patient with acute irreversible hemorrhage has been hypotensive for an extended period and cannot be resuscitated despite fluid administration and use of vasoactive drugs.²³ Presumed mechanisms in this situation include microcirculatory failure with loss of vasomotor response and integrity of the vascular bed. Patients with subacute but ultimately irreversible shock can be resuscitated initially, but progressive organ injury and end-organ dysfunction follow.

INFLAMMATION IN SHOCK AFTER INJURY

In addition to blood loss, extensive research suggests that trauma may be considered an inflammatory disease.²⁴⁻²⁷ It has been shown that a variety of mediators and indicators of inflammatory response are elevated in severely injured patients. For many of these factors, it could be shown that they were significantly elevated in patients eventually dying compared with survivors, and that prediction of outcome is possible with a significant degree of accuracy. Peak inflammatory activity as measured by plasma values has been noted within hours of injury. Although it cannot at present be decided which of these parameters may play a direct pathophysiologic role in development and promotion of inflammatory response and consecutive organ dysfunction, and which is an indicator of this reaction, inflammatory mediators may reflect pathophysiologically relevant disturbances set off by tissue injury and blood loss with consecutive ischemia and reperfusion incidents.²⁸

Shock after trauma differs from pure hypovolemic shock in that effects of release of mediators by tissue injury are superimposed on hypovolemia. It also is clear that not all damage after shock is the result of tissue hypoxia, and that much of cellular damage follows reperfusion and subsequent inflammation. Loci of this inflammatory response are the wound, with activation of macrophages and production of proinflammatory mediators, and the microcirculation, with activation of blood elements and the endothelium.^{28,29}

CELLULAR ENERGETICS

With blood loss, classic circulatory variables, such as systolic blood pressure, remain normal or supranormal until 30% of blood loss occurs.^{2,30} With progressive cellular hypoxia, mitochondria still may be able to metabolize oxygen.² Nonetheless, with significant hypovolemia, total oxygen available to tissue is severely reduced, causing anaerobic metabolism, which is energy inefficient because one molecule of glucose is no longer able to contribute to resynthesis of 32 mol of adenosine triphosphate but only to 2 mol. Glucose must reach cells through the circulation, which is critically reduced. In addition, the end product is no longer carbon dioxide, which can be eliminated by ventilation, but lactic acid and hydrogen ions, leading to metabolic acidosis. Acidosis drives cellular swelling with loss of extracellular fluid volume into the cells. Lactate finally is metabolized by the liver, which also is hypoxic. Transcapillary refill and lymph flow direct interstitial fluid to increase the circulating blood volume, but ultimately capillaries are damaged by hypoxia and the action of activated neutrophils, which increases interstitial edema. Finally, autoregulation of microcirculation is destroyed, leading to fluid sequestration and sludging in the microvasculature. These factors are responsible for increased diffusion distance for oxygen from capillaries to the mitochondria, which further impairs oxygen extraction. Tissue hypoxia also is the most potent stimulus for proinflammatory activation of macrophages and release of vasoactive or arachidonic acid metabolites, such as

prostaglandins and thromboxane. Hypovolemia, shock, and any other cause of brain hypoxia also are detrimental to recovery, particularly in patients with head injury because these conditions induce secondary brain damage.

IMMUNE MEDIATOR CASCADES

Although a variety of initiating events may occur, the subsequent inflammatory response is qualitatively similar.² Local activation of the complement cascade produces anaphylatoxins, which are strong attractants and stimulants of neutrophils. Local endothelium expresses endothelial leukocyte adhesion molecules, which attract the neutrophil population. Activated neutrophils also express adhesion molecules, leading to aggregation, margination in the vascular endothelium, and migration through vessel walls at the area of injury. This inflammatory response produces a respiratory burst with formation of oxygen radicals and synthesis of proteolytic enzymes (elastase). Local release of bradykinin, histamine, and prostaglandin induces local vasodilation and increased capillary permeability from macromolecules, resulting in a protein-rich exudate. Local phagocytes release messenger molecules, such as granulocyte-macrophage colony-stimulating factor and macrophage colony-stimulating factor, which activate the bone marrow to produce more inflammatory cells. Neutrophils injure otherwise healthy tissues.^{2,31-34}

In a slower response, the monocyte population is attracted to the site of injury, where it differentiates to macrophages and contributes to the inflammatory process by phagocytosing and killing bacteria or disposing of necrotic tissue or both. Macrophages are activated further by triggers such as hypoxia or C5a, macrophage-activating factor, and interleukin (IL)-1-like activity from neutrophils. On stimulation, macrophages release a variety of classes of secretory products, which may be proinflammatory (proteolytic enzymes, oxygen radicals, IL-1, IL-6, tumor necrosis factor) or anti-inflammatory (IL-10, prostaglandin E₂). Macrophage mediators such as prostaglandin E₂, tumor necrosis factor, IL-1, IL-2, and IL-6 provide systemic signals adapting metabolic and defense mechanisms. Macrophages take several days after activation to develop full inflammatory capacity. They also may release nitric oxide and cytotoxic radicals. In the setting of injury, this local inflammatory process spills over to cause an exaggerated systemic response with inflammatory damage to otherwise healthy cells and organs distant to the site of injury. Secondary infection may occur in the compromised host, leading to generalized inflammation and multiorgan dysfunction (Box 27.1).^{2,35,36}

NEUROIMMUNE RESPONSE TO TRAUMA

More recent work examines the link between the autonomic nervous system and modulation of immune response during traumatic injury. Anatomic interactions with immune-competent cells have been identified, and functional consequences of this interaction in the host are now being examined. Integrated hemodynamic, metabolic, behavioral, and immune responses allowing host adaptation are the stress response.³⁷⁻⁴¹

Tumor necrosis factor- α if sepsis

*A variety of inflammatory mediators are associated with soft tissue injury, bony injury, and blood loss associated with various forms of trauma. The time course of mediator appearance in limited studies done to date is suggested in this box. In experimental models and limited clinical data, the presence of soft tissue or bony injury in addition to hemorrhage accelerates and magnifies the production of these mediators over clinical and experimental models in which hemorrhage alone is seen.

From Goris RJ: Pathophysiology of shock in trauma. *Eur J Surg* 2000;166:100-111.

Catecholamines are neurotransmitters that affect immune response humorally through circulating adrenal-derived epinephrine and locally through neuronal release of norepinephrine. There is anatomic evidence of central nervous system (CNS)–lymphoid organ connection through autonomic and sensory fibers and immune tissues, including bone marrow, thymus, spleen, and lymph nodes.³⁷ This sympathetic innervation of lymphoid organs is found across species and has been confirmed by immunohistochemistry. In bone marrow, myelinated and nonmyelinated fibers are distributed with vascular plexuses where they influence hematopoiesis and cell migration. In the lungs, noradrenergic nerve fibers supply tracheobronchial smooth muscle and glands. In addition, nerve fibers have been shown throughout the different compartments of the bronchus-associated lymphoid tissue forming close contact with mast cells, cells of the macrophage/monocyte lineage, or other lymph node cells. In the thymus, noradrenergic nerve fibers have been localized in the subcapsular, cortical, and corticomedullary regions associated with blood vessels and

intralobular septa branching into cortical parenchyma where they reach to thymocytes.^{37,42}

The functional effects of catecholamines on cells of the immune system have been confirmed in human volunteers. In addition, relevance of this control mechanism and the implications for dysregulation have been shown by rapid systemic release of IL-10 and the high incidence of infection in patients with sympathetic storm from accidental or iatrogenic brain trauma.³⁷ Although detrimental effects of sustained and exaggerated sympathetic nervous system activation on cardiovascular and metabolic homeostasis have long been recognized, attention is now directed to the likelihood of immune dysregulation as well.

The neuroimmune axis is a bidirectional network composed of descending pathways linking the CNS to peripheral immune tissues and a parallel afferent arm linking the immune system with the CNS. The integrity of this loop allows for communication between the CNS and peripheral immune system integrating neuronal and immune signals in the periphery and in the CNS. Cells from the immune system express functional receptors and signal transduction pathway components for several neuroendocrine mediators allowing functional cellular responses to agonist stimulation. Similarly, cells in the CNS are capable of synthesizing, secreting, and responding to inflammatory and immune molecules. There is considerable evidence that the peripheral immune system can signal the brain to elicit a sickness response during infection, inflammation, and injury. Peripheral immune molecules such as cytokines influence CNS action through mechanisms including entry into the brain through a saturable transport mechanism or through areas that lack the blood-brain barrier. Afferent neurons of the vagus nerve also are activated (Fig. 27.1).⁴³⁻⁴⁵

Severe trauma is characterized by the classic activation of the sympathetic nervous system and the recently recognized contribution of the inflammatory and neuroimmune response to injury.³⁷ The sympathetic nervous system has significant anatomic and functional interaction with cells of the immune system and plays an important role in control of the magnitude of early inflammatory response to injury by ensuring expression of adequate cytokine balance.³⁷ Sympathetic neural pathways exert direct effects on cells of the immune system, affecting cytokine expression, lymphocyte function, and cytotoxic activity. In return, the inflammatory mediators released communicate with the CNS through stimulation of sensory and vagal afferents or by crossing the blood-brain barrier through active transport mechanisms and pathways allowing access to hypothalamic-pituitary structures. Immune-derived mediators, such as cytokines and chemokines, can modulate neurotransmission affecting activation of descending autonomic and neuroendocrine pathways.³⁷

ACUTE COAGULOPATHY AFTER TRAUMA

HISTORICAL PERSPECTIVE

Hemorrhagic shock accounts for a significant number of deaths in patients arriving at hospital with acute injury. Patients with uncontrolled hemorrhage continue to die despite adoption of new surgical techniques with improved

Figure 27.1 Endocrine, neurologic, and immunologic response to injury is linked through afferent and efferent arcs as described in the text and drawn in this figure. Patients sustaining blunt injury or soft tissue loss in addition to hemorrhage show clinical evidence of increased cytokine and inflammatory mediator production with acceleration of the process described here. The best clinical data in support of this pair of arcs come from patients with traumatic brain injury. CNS, central nervous system; IL-1, interleukin 1; IL-6, interleukin 6; NK, natural killer; TNF, tumor necrosis factor. (From Molina PE: Neurobiology of the stress response: Contribution of the sympathetic nervous system to the neuroimmune axis in traumatic injury. *Shock* 2005;24:3-10.)

transport and emergency care.^{46,47} Coagulopathy, occurring even before resuscitation, contributes significantly to the morbidity associated with bleeding.^{48,49} Recognition of the morbidity associated with bleeding and coagulation abnormality dates to the Vietnam conflict. At that time, standard tests including prothrombin time (PT) and partial thromboplastin time (PTT) correlated poorly with effectiveness of acute resuscitation efforts. Similar work in the late 1970s was performed in civilian patients receiving massive transfusion. Again, PT, PTT, and bleeding time were only helpful if markedly prolonged.^{50,51}

Studies in the 1970s and 1980s provided additional detail regarding the limitation of simple laboratory parameters and factor levels.^{51,52} In a study of multiple patients requiring massive transfusion, platelet counts fell in proportion to the size of transfusion although factors V and VIII correlated poorly with the volume of blood transfused. Where coagulopathy appeared, patients seemed to respond to platelet administration. In subsequent studies, patients receiving a large number of blood products were followed for microvascular bleeding. Moderate deficiencies in clotting factors were common, but they were not associated with microvascular bleeding. Microvascular bleeding was associated with severe coagulation abnormalities such as clotting factor levels less than 20% of control values. In statistical analysis, clotting factor activities less than 20% of control levels were predicted by significant prolongation of PT and PTT. These earlier investigators also suggested that empiric blood replacement formulas available at the time were not likely to prevent microvascular bleeding because consumption of platelets or clotting factors did not consistently appear and simple dilution caused by resuscitation

fluids frequently did not correspond to microvascular bleeding.⁵²

The attention of the American trauma community was drawn to coagulopathy after trauma with the description of the “bloody vicious cycle” by the Denver health team over 20 years ago.⁴⁸ These investigators noted the contribution of hypothermia, acidosis, and hemodilution associated with inadequate resuscitation and excessive use of crystalloids. Subsequent work extended these observations describing early coagulopathy that could be independent of clotting factor deficiency.⁵³ In a more recent trial, early coagulopathy was noted in the setting of severe injury, which was present in the field, prior to emergency department arrival and initiation of fluid resuscitation. Coagulopathic patients were at increased risk for organ failure and death.

In a study questioning historical transfusion practice emphasizing administration of packed red blood cells (PRBCs) in the setting of massive trauma, Hirshberg and coworkers, using clinical data, developed a computer model designed to capture interactions between bleeding, hemodynamics, hemodilution, and blood component replacement during severe hemorrhage. Resuscitation options were offered in this model and their effectiveness evaluated.⁵⁴ After setting thresholds for acceptable loss of clotting factors, platelets, and fibrinogen, the authors modeled behavior of coagulation during rapid exsanguination without clotting factor or platelet replacement. The PT reached a critical level first followed by fibrinogen and platelets. If patients were resuscitated with small amounts of crystalloid, leaving overall blood volume reduced, the effective life of components in the coagulation cascade was increased. More aggressive fresh frozen plasma (FFP) replacement in the

patient with significant bleeding was supported by this model. The optimal ratio for administration of FFP to PRBCs in this analysis was 2:3. Delayed administration of FFP led to critical clotting factor deficiency regardless of subsequent administration of FFP. Fibrinogen depletion was easier to correct. After administration of 5 units of PRBCs, the hemostatic threshold for fibrinogen was not exceeded if a FFP-to-PRBC ratio of 4:5 was employed. Analysis of platelet dilution demonstrated that even if platelet replacement was delayed until 10 units of PRBCs were infused, critical platelet dilution was prevented with a subsequent platelet-to-PRBC ratio of 8:10.⁵⁴

The essential message of this work is that massive transfusion protocols, emphasizing PRBCs, in existence when this study was performed provide inadequate clotting factor replacement during major hemorrhage and neither prevent nor correct dilutional coagulopathy.

RECENT STUDIES

Brohi and coworkers from the United Kingdom helped to reinvigorate discussion of coagulopathy after injury by adding new coagulation laboratory techniques to previous clinical observations.⁵⁵ After reviewing over 1000 cases, patients with acute coagulopathy after injury had higher mortality rates throughout the spectrum of Injury Severity Scores (ISS). Contrary to historical teaching that coagulopathy was a function of hemodilution with massive crystalloid resuscitation, these authors noted that the incidence of coagulopathy increased with severity of injury but not necessarily in relationship to the volume of intravenous fluid administered to patients. Brohi and others helped to reemphasize the observation that acute coagulopathy could occur before significant fluid administration, which was attributable to the injury itself and proportional to the volume of injured tissue. Development of coagulopathy was an independent predictor of poor outcome. Mediators associated with tissue trauma including humoral and cellular immune system activation with coagulation, fibrinolysis, complement, and kallikrein cascades have been associated with changes in hemostatic mechanisms similar to those identified in the setting of sepsis.⁵⁵⁻⁵⁷

Factors contributing to coagulopathy in the setting of injury have been further reviewed.⁵⁸ Hypothermia relates to development of coagulopathy by reduction in platelet aggregation and decreased function of coagulation factors in nondiluted blood. Patients with temperature reduction below 34°C had elevated PT and PTT. Coagulation, like most biologic enzyme systems, works best at normal temperature. Similarly, acidosis occurring in the setting of trauma as a result of bleeding and hypotension also contributes to clotting failure. Animal work shows that a pH less than 7.20 is associated with hemostatic impairment. Platelet dysfunction and coagulation enzyme system changes are noted when blood from healthy volunteers is subjected to an acidic environment.^{59,60}

We are now seeing that with or without hypothermia and acidosis, posttraumatic coagulopathy may develop in a significant number of patients. Although dilution-driven coagulopathy must be considered, loss of clotting factors has been associated with exaggerated inflammation in association with injury.

Hess and coworkers, as part of an international medical collaboration, developed a literature review to increase awareness of coagulopathy independent of crystalloid administration following trauma.⁵⁷ The key initiating factor is volume of tissue injury. Patients with severe tissue injury but no physiologic derangement, however, rarely present with coagulopathy and have a lower mortality rate.^{61,62} Tissue damage initiates coagulation as endothelial injury at the site of trauma leads to exposure of subendothelial collagen and activation of the coagulation cascade.

Hyperfibrinolysis is seen as a direct consequence of the combination of tissue injury and shock. Endothelial injury accelerates fibrinolysis because of direct release of tissue plasminogen activator.^{57,63} Tissue plasminogen activator expression by endothelium is increased in the presence of thrombin. Fibrinolysis is accelerated because of the combined effects of endothelial tissue plasminogen activator release with ischemia and inhibition of plasminogen activator inhibitor in shock. Although hyperfibrinolysis may focus clot propagation on sites of actual vascular injury, with widespread insults, this localization may be lost.

A number of important cofactors must be present to stimulate coagulopathy in the setting of injury.⁵⁷ Shock is a dose-dependent cause of tissue hypoperfusion. Elevated base deficit has been associated with coagulopathy in as many as 25% of patients in one large study. Progression of shock appears to result in hyperfibrinolysis. One mediator implicated in coagulopathy after injury is activated protein C. Immediate postinjury coagulopathy is likely a combination of effects caused by large volume tissue trauma and hypoperfusion (Fig. 27.2).⁵⁷

As will be discussed later, equivalent ratios of FFP, PRBCs, and platelets are now considered for management of significant hemorrhage with coagulopathy after injury. Hypothermia and acidemia must be controlled to reduce their impact on enzyme systems.⁶⁴ Similar to sepsis, cross-talk has been noted between coagulation and inflammation systems with injury. Activation of coagulation proteases may induce inappropriate inflammation with activation of cascades such as complement and platelet degranulation.^{65,66} Trauma patients are initially coagulopathic with increased bleeding. This condition may progress to a hypercoagulable state, putting them at risk for thrombotic events. This late thrombotic state bears similarities with coagulopathy of severe sepsis and depletion of protein C. Injured and septic patients share a propensity toward multiple organ failure and prothrombotic states.^{67,68}

FLUID THERAPY

Warmed isotonic electrolyte solutions are recommended for initial resuscitation of traumatic shock by the Committee on Trauma of the American College of Surgeons. This type of fluid provides transient intravascular expansion and stabilizes the intravascular volume by replacing accompanying fluid losses into the interstitial and intracellular spaces. Lactated Ringer's solution is the initial fluid of choice. Normal saline is the second choice. Normal saline has the potential to cause hyperchloremic acidosis. This complication is more likely if renal function is compromised (Table 27.1).⁶⁹

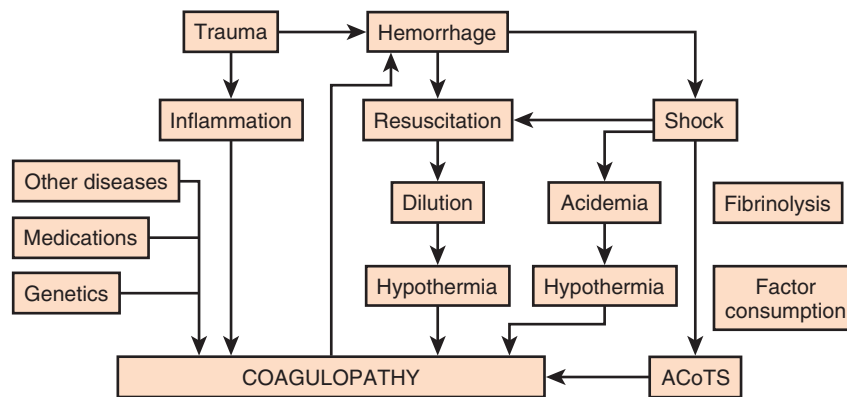

Figure 27.2 A diagram showing some of the mechanisms leading to coagulopathy in the injured. Trauma can lead to hemorrhage, which can lead to resuscitation, which in turn leads to dilution and hypothermia causing coagulopathy and further hemorrhage. This is classic “dilution coagulopathy.” Hemorrhage can also cause shock, which causes acidosis and hypothermia that in turn lead to coagulopathy, the “fatal triad.” Trauma and shock can also cause the acute coagulopathy of trauma shock (ACoTS) associated with factor consumption and fibrinolysis. Coagulopathy is further associated with trauma-induced inflammation and modified by genetics, medications, and acquired diseases. (From Hess JR, Brohi K, Dutton RP, et al: The coagulopathy of trauma: A review of mechanisms. *J Trauma* 2008;65:748-754.)

Table 27.1 Estimated Fluid and Blood Losses Based on Initial Clinical Presentation*

Clinical Finding	Class I	Class II	Class III	Class IV
Blood loss (mL)	≤750	750-1500	1500-2000	>2000
Blood loss (% blood volume) ≤15%	15-30%	30-40%	>40%	
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/h)	>30	20-30	5-15	Negligible
Central nervous system/mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

*This is the standard approach to resuscitation of shock after injury as described in the Advanced Trauma Life Support course promulgated by the Committee on Trauma of the American College of Surgeons. The crystalloid of choice used in resuscitation is lactated Ringer's solution. Clinical parameters are used to estimate the degree of blood loss, and fluid resuscitation begins with 1-2 L of lactated Ringer's solution given through large-bore peripheral intravenous lines. When the response to resuscitation is limited or transient, O-negative or type-specific blood is added to resuscitation while the cause of shock is sought and additional treatment is given.

From American College of Surgeons Committee on Trauma: Advanced Trauma Life Support for Doctors, 7th ed. Chicago, American College of Surgeons, 2004, pp 69-85.

An initial warm fluid bolus is given rapidly—usually 1 to 2 L for an adult and 20 mL/kg for a child.⁴⁵ Patient response is observed during this initial fluid resuscitation, and subsequent therapeutic decisions are based on this response. The required amount of fluid and blood is difficult to predict on initial evaluation of the patient. A rough guideline promulgated by the American College of Surgeons for the total amount of crystalloid volume acutely required is 3 mL of crystalloid fluid to replace each 1 mL of blood loss, allowing for restitution of plasma volume lost into interstitial and intracellular spaces. It is most important, however, to assess patient response to fluid resuscitation and evidence of adequate end-organ perfusion as measured by urine output and level of consciousness, rather than provide fluid based on a specific formula. If the amount of fluid required to restore or maintain adequate end-organ function exceeds the previously mentioned estimates, careful reassessment of the situation and exploration for unrecognized injuries, bleeding, or other causes of shock are necessary (Table 27.2).

In clinical practice, large volume resuscitation with lactated Ringer's solution has become common in trauma care.⁷⁰ However, recent military and laboratory work features a growing concern about tissue edema from large volume resuscitation. In recent decades, a persisting picture of acute lung injury due to increased filtration across pulmonary microcapillaries with pulmonary inflammation emerged. This process would later be called the acute respiratory distress syndrome.⁷¹ Other observations included increased interstitial fluid of gut and heart tissues, abdominal compartment syndrome, extremity compartment syndrome in uninjured extremities, and pericardial effusion.^{72,73}

Hemorrhage is a multifactorial disease; circulatory and inflammatory effects of hemorrhagic shock occur simultaneously. Unfortunately, laboratory studies have repeatedly shown that the choice of resuscitation fluid may worsen hemorrhage-induced cellular dysfunction, immune modulation, and inflammation. Fluids affect neutrophil activity by

Table 27.2 Responses to Initial Fluid Resuscitation*

Factor	Rapid Response	Transient Response	No Response
Vital signs	Return to normal	Transient improvement, recurrence of decreased blood pressure and increased heart rate	Remain abnormal
Estimated blood loss	Minimal (10-20%)	Moderate and ongoing (20-40%)	Severe (>40%)
Need for more crystalloid	Low	High	High
Need for blood	Low	Moderate to high	Immediate
Blood preparation	Type and crossmatch	Type-specific	Emergency blood release
Need for operative intervention	Possibly	Likely	Highly likely
Early presence of surgeon	Yes	Yes	Yes

*The Advanced Trauma Life Support course advocates ongoing evaluation of patient response to initial fluid administration. Patients with no response frequently require emergent blood transfusion and transfer to the operating room. Patients with transient response also frequently require operative intervention. Most patients, particularly in centers seeing blunt injury, respond rapidly to an initial 1-2 L of crystalloid and are cleared to proceed to more detailed imaging to determine internal injuries after normalization of clinical parameters. From American College of Surgeons Committee on Trauma: Advanced Trauma Life Support for Doctors, 7th ed. Chicago, American College of Surgeons, 2004, pp 69-85.

changing life span, activation, and gene expression. Resuscitation fluids also enhance inflammatory cascade through upregulation of cellular receptors and proinflammatory mediators. The choice of fluid also affects cellular gene expression, apoptotic cell death, and extracellular matrix integrity.^{70,74-76}

ISOTONIC CRYSTALLOIDS

Of isotonic crystalloids, lactated Ringer's solution has been most extensively studied to determine its role in hemorrhage-induced immune dysfunction, inflammation, and management of ischemia and reperfusion injury. Lactated Ringer's solution has been shown to upgrade vascular endothelial adhesion molecules and to increase expression of CD11b and CD18 binding sites on neutrophils. Neutrophil oxidative burst is also stimulated by lactated Ringer's solution. In other organs, Ringer's lactate has been found to increase apoptosis in the bowel, the liver, and the lung with multiple cell types affected including macrophages, endothelial cells, epithelial cells, and smooth muscle cells.^{70,77}

Despite laboratory findings about the dangers of lactated Ringer's solution, it remains the fluid of choice in many centers and the recommended fluid of the Advanced Trauma Life Support (ATLS) protocol. Efforts have been made to examine why lactated Ringer's solution is cytotoxic and identify ways to improve it. Traditionally, lactated Ringer's solution came in racemic form; laboratory work implicates the D-isomer of lactate as its primary toxic component.⁷⁸ The D-isomer was found to increase neutrophil oxidative burst, enhance apoptosis, and drive inflammation. The L-isomer of lactate may confer immune protection through attenuation of neutrophil activation, alteration of leukocyte gene expression, and reduction in apoptosis.^{79,80}

COLLOIDS

Hyperoncotic colloid solutions have also been studied in resuscitation roles for traumatic hemorrhage. The natural

colloid albumin does not induce neutrophil oxidative burst and may confer a protective immunologic effect by decreasing neutrophil expression of adhesion molecules.⁸¹ At present, albumin sees little application in resuscitation at the scene of injury but has been investigated in critical care practice.

An artificial colloid, 6% hetastarch, has been found to have a number of deleterious resuscitation effects in animal models including increased neutrophil oxidative burst and pulmonary apoptosis. Beneficial effects include decreased neutrophil migration. At present, natural and artificial colloids have failed to show clinical benefits in comparison with crystalloid solutions.^{82,83} Laboratory concerns and lack of a positive clinical outcomes mandate argue against the use of colloids in early resuscitation of hemorrhagic shock.

Recent reviews suggest important differences in safety among colloids. Examination of data comparing colloids with crystalloids must take into account materials employed. When albumin was used as a reference, the incidence ratio for anaphylactoid reactions was 4.51 after administration of hydroxyethyl starch, 2.32 after dextran, and 12.4 after gelatin. Artificial colloid administration was consistently associated with coagulopathy and clinical bleeding, most frequently in cardiac surgery patients receiving starches. Albumin had the lowest rate of total adverse events and serious adverse events.⁸⁴ Although albumin is isolated from human plasma, no evidence of viral disease transmission has been consistently identified. Life-threatening anaphylactoid reactions were infrequent for all colloids. Hydroxyethyl starch, as compared with albumin, more than quadrupled the incidence of anaphylactic reactions, whereas dextran more than doubled them. The incidence of these reactions in recipients of gelatin was greater by an order of magnitude than after albumin infusion. Because artificial colloids are derived from nonhuman source materials, they may be recognized as foreign and are more likely to provoke this immune-mediated response. The foreign nature of artificial colloids also may hinder metabolic clearance and promote tissue deposition. On the basis of extensive evidence, albumin is the safest colloid for consideration in

resuscitation of traumatic shock.⁸⁴ Although factors such as desirability of anticoagulant activity may favor other artificial colloids, this is not true in the setting of injury.⁸⁵⁻⁸⁷

Multicenter data comparing albumin and saline for fluid resuscitation were obtained in Australia and published in 2004.⁸⁸ Nearly 7000 patients were randomly assigned to administration of 4% albumin or normal saline for intravascular fluid resuscitation procedures. Mortality rate and the incidence of single and multiple organ dysfunction were comparable in the two groups. Subset analysis suggests, however, poorer outcomes in the setting of injury. In the subgroup of 140 patients included with principal diagnoses of trauma, a treatment effect seemed to favor administration of saline. In this trial, the increased relative risk of death among patients with trauma compared with patients without trauma resulted from an excess number of deaths among patients who had trauma with brain injury. The difference in mortality rates between albumin and saline groups among patients with trauma involving brain injury must be viewed cautiously because the number of involved subjects is small. In the Australian trial, patients with traumatic brain injury constituted only 7% of the study population, and the excess number of deaths in the albumin group was 21. Other parameters that could be helpful in evaluation of the impact of albumin in the setting of brain injury, such as functional neurologic status, were not provided. In contrast with the experience in trauma, the Australian trial suggests some evidence of treatment benefit favoring administration of albumin in patients with severe sepsis. Given contemporary resuscitation technology, factors influencing the choice of resuscitation for critically ill patients include specific clinician concerns, treatment tolerance, safety, and cost.

HYPERTONIC SALINE

Increased transmembrane sodium gradient caused by hypertonic saline generates intravascular volume expansion similar to hyperoncotic colloids and superior to conventional isotonic crystalloids such as lactated Ringer's solution and normal saline. Animal models suggest that hypertonic saline solutions dilate precapillary arterioles and shunt oxygen to vital organs.^{89,90} Hypertonic saline solutions also have fewer proinflammatory properties than other clinical crystalloids and colloids. Hypertonic saline does not induce expression of inflammatory cytokine receptor genes in multiple studies and blunts hemorrhage-induced increase in plasma levels of proinflammatory cytokines, IL-10, and granulocyte-macrophage colony-stimulating factor. Hypertonic saline also does not increase apoptotic cell death in liver, lung, or bowel.⁷⁰

What about the impact of hypertonic saline and associated hypernatremia on head injury?⁹¹ Studies in experimental animals and humans suggest that hypertonic saline may be highly effective in treating head injury, either alone or associated with hemorrhagic hypotension. Tissue swelling in a closed cranium threatens to cause major pressure-induced brain damage or death, and concomitant hemorrhage hypotension reduces cerebral oxygen delivery, resulting in a secondary ischemic insult. Historical data suggest a twofold higher incidence of adverse outcomes in patients with brain injury combined with hypotension. Early data suggest that

patients treated with hypertonic saline with dextran are more likely to survive to discharge than individuals treated with standard resuscitation care.^{92,93}

Despite laboratory data suggesting that hypertonic saline may be an effective tool in resuscitation-induced injury, mixed clinical data have not led to widespread utilization of this material.

HYPERTONIC-HYPERONCOTIC FLUIDS

Mixture of hypertonic saline with dextran has been the most extensively tested hypertonic-hyperoncotic fluid.⁷⁰ Use of combinations of hypertonic saline and dextran suggests that this material is effective in expanding plasma volume, restoring hemodynamics, and improving microcirculatory perfusion. In the laboratory, hypertonic saline and dextran solutions blunt hemorrhage-induced inflammatory response by neutrophils and, in clinical trials, decreased adhesion molecule expression.⁹⁴ As with hypertonic saline solutions, there has been concern that hypertonic saline mixed with dextran could accelerate hemorrhage, increase mortality rate, and cause hypernatremia and hyperchloremia.⁹⁵ Despite multiple clinical trials comparing hypertonic saline and dextran solutions to more traditional resuscitation products, no improvement in mortality rate or change in the pattern of organ failure is seen.⁹⁶

Mechanisms by which hypertonic/hyperoncotic resuscitation may be effective in models of head injury and hemorrhage show reduction in water content in noninjured portions of the brain with reduction in intracranial pressure and cerebral edema. In a large animal model, when hypertonic saline was compared with a synthetic colloid, colloid alone had no effect on brain water content.^{97,98}

The optimal crystalloid/nonblood colloid resuscitation fluid or regimen has yet to be defined. Hypertonic solutions remain on the horizon of opportunity owing to rapid expansion of plasma volume and improvement of hemodynamics, expanding the therapeutic window until patients may be transported to definitive treatment. Optimally, resuscitation as applied clinically and studied in the preclinical setting must be titrated to desired physiologic and metabolic performance objectives.

CRYSTALLOIDS VERSUS COLLOIDS

Plasma and blood were the fluid replacements of choice in traumatic shock until the early 1960s, when a variety of investigators showed the need to replace the extracellular fluid deficit with crystalloid solutions. These observations were followed by a variety of clinical studies comparing colloid, typically albumin, solutions with crystalloids, typically lactated Ringer's solution. Consistent with early studies, colloids, when given on an equal volume basis, more effectively increase cardiac output and oxygen transport. Another finding of this early work was the need to give crystalloids in far greater quantities than colloids to achieve consistent hemodynamic objectives.^{99,100}

Later studies from the Vietnam era compared resuscitation of patients who were given whole blood and crystalloids with patients given whole blood plus 5% albumin. Fluid infusion volumes were far higher in the patients given crystalloid solutions. There was no evidence of pulmonary

edema, and patients treated with crystalloids seemed to fare better than patients treated with resuscitation containing albumin. Albumin seemed to have less effect on restoration of renal function with suggestion of detrimental effects in pulmonary response, myocardial contractility, and coagulation. Large animal models suggested that pulmonary compromise could relate to increased capillary permeability to albumin. Increased losses of albumin to the heart, kidneys, liver, and brain also were reported.^{99,101} More extensive studies in injured patients supported reservations regarding the use of albumin. Evaluation of patients randomly selected to receive 150 g of albumin per day intraoperatively and postoperatively noted poorer outcomes than in patients receiving lactated Ringer's solution. Both groups received whole blood and FFP. Patients treated with albumin required greater ventilator support and had poorer oxygenation.^{99,102,103} In another carefully conducted trial of patients with multiple trauma, no differences in cardiopulmonary function between patients resuscitated with lactated Ringer's solution and patients given 5% albumin and lactated Ringer's solution were identified.¹⁰⁴ Normal cardiac index was used as a therapeutic end point. To maintain adequate cardiac output, patients who received crystalloids required far more resuscitation volume than patients treated with albumin. These authors concluded that cardiac output was an appropriate end point for resuscitation, and that no advantage was accrued based on the type of fluid employed. A clear cost advantage of crystalloids was identified.⁹⁹

Guyton and Lindsey¹⁰⁵ examined the effect of colloid oncotic pressure on pulmonary edema. They observed that reducing the serum protein level lowered the threshold of left atrial pressure at which pulmonary edema could occur. Zarins and colleagues¹⁰⁶ subsequently showed that a low colloid oncotic pressure alone did not cause an elevation in extravascular lung water. Because of the remarkable efficiency of pulmonary lymphatics, arterial blood gases, shunt fraction, and lung compliance were unchanged despite a 14% increase in body weight caused by infusion of lactated Ringer's solution to keep high pulmonary artery occlusion pressures. No pulmonary edema was created despite the presence of ascites and marked peripheral edema. Demling and coworkers¹⁰⁷ confirmed these findings with a chronic lung lymph fistula in sheep. Holcroft and coworkers¹⁰⁸ produced pulmonary edema in baboons during resuscitation from hemorrhage by continuously administering large volumes of lactated Ringer's solution sufficient to elevate pulmonary artery occlusion pressures 15 mm Hg above baseline levels. With cessation of infusion, filling pressure rapidly returned to normal.

BLOOD COMPONENT THERAPY

Despite work from multiple groups suggesting that simple replacement of PRBCs was not a sufficient answer for the most severely injured patient, particularly in the setting of coagulopathy, the concept of combination blood component replacement remained outside the mainstream of trauma care for over 20 years.^{48,52,109} It took armed conflicts and experience in a multinational group of trauma centers

to bring awareness of the need for multiple blood component therapy in massive bleeding to the level of general trauma practice.

The 1970s and 1980s saw several groups propose resuscitation of significant hemorrhage with combinations of blood components. Kashuk and Moore proposed multicomponent blood therapy in patients with significant vascular injury.⁴⁸ In a study of patients with major abdominal vascular injury, Kashuk and coworkers noted frequent deviation from a standard ratio of 4:1 or 5:1 for units of PRBCs to units of FFP. The ratio was 8:1 in nonsurvivors and 9:1 where overt coagulopathy was noted. Fifty-one percent of patients in this series were coagulopathic after vascular control was obtained. Using multivariate analysis, Ciavarella and coworkers from the Puget Sound Blood Center and Harborview Medical Center proposed aggressive supplementation of platelets in the setting of massive transfusion. These investigators noted that platelet counts below $50 \times 10^9/L$ correlated highly with microvascular bleeding in trauma and surgery patients. Fibrinogen repletion was also emphasized. Guides to resuscitation included fibrinogen level, PT, and PTT. Supplemental FFP or cryoprecipitate was recommended for low fibrinogen levels.⁵² Lucas and Ledgerwood, summarizing extensive preclinical and clinical studies, suggested administration of FFP after 6 units of PRBCs had been infused. Additional FFP was recommended for every five additional PRBC transfusions. Monitoring included platelet count, PT, and PTT after each 5 units of PRBCs are administered. Platelet transfusion is generally unnecessary unless the platelet count falls below 50,000.¹⁰⁹

Rhee and coworkers, using the massive database of the Los Angeles County Level I Trauma Center, examined transfusion practices in 25,000 patients.¹¹⁰ Approximately 16% of these patients received a blood transfusion. Massive transfusion (≥ 10 units of PRBCs per day) occurred in 11.4% of transfused patients. After excluding head-injured patients, these authors studied approximately 400 individuals. A trend toward increasing FFP use was noted during the 6 years of data that were reviewed (January 2000 to December 2005). Logistic regression identified the ratio of FFP to PRBC use as an independent predictor of survival. With a higher ratio of FFP:PRBC, a greater probability of survival was noted. The optimal ratio in this analysis was an FFP:PRBC ratio of 1:3 or less. Rhee and coworkers provide a large retrospective data set demonstrating that earlier more aggressive plasma replacement can be associated with improved outcomes after bleeding requiring massive transfusion. Ratios derived in this massive retrospective data review support the observations of Hirshberg and coworkers.⁵⁴ Like the data presented by Kashuk and coworkers in another widely cited report, this retrospective data set suggests improved clinical outcome with increased administration of FFP.¹¹¹

Another view of damage control hematology comes from Vanderbilt University Medical Center in Nashville, Tennessee. This group implemented a trauma exsanguination protocol involving acute administration of 10 units PRBC with 4 units FFP and 2 units platelets. In an 18-month period, 90 patients received this resuscitation and were compared to a historical set of control subjects. The group of patients

receiving the trauma exsanguination protocol as described by these investigators had lower mortality rates, higher blood product use in initial operative procedures, and more frequent use of products in the initial 24 hours, though overall blood product consumption during hospitalization was decreased.¹¹²

The strongest multicenter civilian data report examining the impact of plasma and platelet administration along with red blood cells on outcome in massive transfusion comes from Holcomb and coworkers.¹¹³ These investigators report over 450 patients obtained from 16 adult and pediatric centers. Overall survival in this group is 59%. Patients were gravely ill as reflected by an admission base deficit of -11.7 , pH 7.2, Glasgow Coma Scale score of 9, and a mean ISS of 32. Examination of multicenter data reflects an improvement in outcome as the ratio of FFP to PRBCs administered approaches 1. FFP, however, is not the sole solution to improved coagulation response in acute injury. These workers also examined the relationship of aggressive plasma and platelet administration in these patients. Optimal outcome in this massive transfusion group was obtained with aggressive platelet as well as plasma administration. Worst outcomes were seen when aggressive administration of plasma and platelets did not take place. When either FFP or platelets were given in higher proportion in relationship to PRBCs intermediate results were obtained. Not surprisingly, the cause of death that was favorably affected was truncal hemorrhage.

A summary statement comes from Holcomb and a combination of military and civilian investigators.^{56,57} These workers identify a patient group at high risk for coagulopathy and resuscitation failure due to hypothermia, acidosis, hypoperfusion, inflammation, and volume of tissue injury. In the paradigm proposed by these writers, resuscitation begins with prehospital limitation of blood pressure at approximately 90 mm Hg preventing renewed bleeding from recently clotted vessels. Intravascular volume resuscitation is accomplished using thawed plasma in a 1:1 or 1:2 ratio with PRBCs. Acidosis is managed by use of THAM (tromethamine) and volume loading with blood components as hemostasis is obtained. A massive transfusion protocol for these investigators included delivery of packs of 6 units of plasma, 6 units of PRBC, 6 units of platelets, and 10 units of cryoprecipitate in stored individual coolers. These coolers are supplied until discontinuation by the trauma team. Even in casualties requiring resuscitation with 10 to 40 units of blood products, Holcomb and coworkers found that as little as 5 to 8 L of crystalloid are utilized during the first 24 hours, representing a decrease of at least 50% compared to standard practice. The lack of intraoperative coagulopathic bleeding allows surgeons to focus on surgical hemorrhage. The goal is arrival of the patient in intensive care unit (ICU) in a warm, euvoletic, and nonacidotic state. International normalized ratio (INR) approaches normal and edema is minimized. Subjectively, patients treated in this way are more readily ventilated and easier to extubate than patients with a similar blood loss treated with standard crystalloid resuscitation and smaller amounts of blood products. Holcomb and others suggest that massive transfusion will be required in 6% to 7% of military patients and 1% to 2% of civilian trauma patients.

END POINTS

THE PROBLEM

Severely injured trauma patients are at high risk of developing multiple organ failure or death. Initial treatment priorities include appropriate fluid administration and rapid hemostasis.^{114,115} Inadequate tissue oxygenation leads to anaerobic metabolism and tissue acidosis. Depth and duration of shock are associated with cumulative oxygen and metabolic debt. Resuscitation is incomplete until the metabolic debt is paid, and tissue acidosis is eliminated with restoration of aerobic metabolism. Many patients seem to be adequately resuscitated based on normalization of vital signs but have occult hypoperfusion and ongoing tissue acidosis (compensated shock). These individuals are at risk for later organ dysfunction and death.⁶⁹

As stated in the Advanced Trauma Life Support protocol, the standard of care remains restoration of normal blood pressure, heart rate, and urine output.⁶⁹ When these parameters remain abnormal (uncompensated shock), the need for additional resuscitation is obvious. After normalization of these parameters, however, many trauma patients still have evidence of inadequate tissue oxygenation or gastric mucosal ischemia. Recognition of this state and its reversal are crucial to reduce the risk of organ dysfunction or death. The optimal marker of adequate resuscitation in injury remains unclear.¹¹⁶

Not all patients can be managed in the same way. More recent literature describing management of neurologic trauma suggests poor outcome with any degree of hypotension during prehospital care, resuscitation, or subsequent in-hospital course. Episodes of hypotension and hypoxia were associated with poor neurologic outcome in a review of more than 700 patients from the Traumatic Coma Data Bank with a Glasgow Coma Scale score less than 9. In this large study, patients without hypotension or hypoxia had a 27% risk of death and a 51% chance of favorable recovery. In the presence of hypotension, with or without hypoxia, the risk of death increased to 65% to 75%. Contrary to the needs of patients with penetrating trauma in whom early aggressive resuscitation may lead to increased bleeding, hypotension should be avoided in head-injured patients. Resuscitation parameters specific to various types of injury have not been reported.¹¹⁷⁻¹¹⁹

OXYGEN DELIVERY PARAMETERS

Shoemaker and various coworkers provided early stimulus to optimization of hemodynamic management in high-risk surgical patients by examining hemodynamic profiles of survivors of surgical shock states versus patients who died.¹²⁰ Survivors had significantly higher oxygen delivery and cardiac index values than nonsurvivors. Values correlating with survival included cardiac index greater than 4.5 L/minute/m², oxygen delivery greater than 600 mL/minute/m², and oxygen consumption equal to or greater than 170 mL/minute/m². These initial observations led to a series of articles from this group suggesting reduction in resource consumption and improvement in morbidity and mortality rates with resuscitation to supranormal oxygen

delivery parameters. Initial augmentation of oxygen delivery came with volume loading followed by dobutamine and blood transfusions as needed to a hemoglobin level of 14 g/dL.¹²¹⁻¹²⁴

Attempts by other investigators to replicate these findings met limited success. Moore and coworkers used a resuscitation protocol aimed at maximizing oxygen delivery and found no benefit with resuscitation to achieve supranormal oxygen delivery.^{116,125} A variety of studies suggested that patients failing to reach resuscitation goals were at increased risk for multiple organ failure. Other workers noted that patients who did not obtain supranormal oxygen delivery values were at high risk of developing organ failure regardless of treatment strategy.^{126,127} Obtaining hemodynamic and oxygen transport parameters seems to be more predictive of survival than useful as a goal for resuscitation, particularly if fluid administration is adequate.

In addition to conflicting outcomes in oxygen transport trials, technical concerns have been raised.¹¹⁶ These studies cannot be totally blinded. Patients in control groups often obtain similar physiologic end points to those in treatment groups. Other aspects of care were sometimes inconsistent, and entrance criteria varied among investigators. There also is potential mathematical coupling of oxygen delivery and consumption because both are calculated values that share many of the same measured variables.¹¹⁷ Some clinicians argue that the pathologic relationship between oxygen delivery and consumption trials cannot be accepted with confidence, unless oxygen consumption is measured directly. Finally, use of traditional oxygen delivery and consumption as resuscitative end points requires a pulmonary artery catheter and special expertise for operation and insertion. Routine use of pulmonary artery catheterization or central venous catheters has not been a part of acute trauma resuscitation or emergency medical management.^{69,116,117}

LACTATE

As an indicator of shock, blood lactate has proved accurate at assessing severity, predicting mortality risk, and assessing response to resuscitation in the hands of various workers.^{116,117} At the cellular level, the explanation is based on oxygen transport principles. With shock and inadequate oxygen delivery, mitochondrial respiration is impaired. The primary cellular fuel, pyruvate, is shunted from its normal aerobic path (conversion by pyruvate dehydrogenase to acetyl coenzyme A and subsequent entry into the tricarboxylic acid cycle) to the anaerobic pathway (conversion to lactate by lactate dehydrogenase). Anaerobic metabolism makes inefficient use of cellular substrate, and high-energy phosphate stores are rapidly depleted. During cellular ischemia, lactate is released into the bloodstream and ultimately converted to glucose in the liver and kidney via the Cori cycle. Because it directly reflects anaerobic metabolism, lactate is thought to serve as a mirror of global hyperperfusion because increasing lactate levels indicate increasing oxygen debt.^{117,128}

Initial and peak lactate levels and duration of increased lactate concentration correlate with development of multi-organ dysfunction after trauma.¹¹⁶ In a study of trauma

patient resuscitation, patients normalizing lactate levels at 24 hours survived, whereas patients who normalized lactate levels between 24 and 48 hours had a 25% mortality rate; patients who did not normalize by 48 hours had an 86% mortality rate.¹²⁹ Theoretically, severity of metabolic acidosis secondary to tissue hyperperfusion should be reflected in lactate levels, anion gap, and base deficit. This is not a consistent finding among investigators studying trauma resuscitation.^{130,131} In addition, although lactate levels are rapidly available, conclusive data tying specific lactate levels and targets to improved resuscitation outcomes are unavailable.

BASE DEFICIT

Inadequate oxygen delivery to tissues leads to anaerobic metabolism. The degree of anaerobiosis is proportional to the depth and severity of hemorrhagic shock, which should be reflected in lactate and base deficit. Arterial pH is not as useful because compensatory mechanisms attempt to normalize this parameter. Serum bicarbonate levels offer better correlation with base deficit (removal or addition of base in the blood).^{116,132,133}

Similar to lactate, base deficit has been carefully studied.¹¹⁶ A greater base deficit has been associated with blood pressure reduction, increased blood loss, and transfusion requirements. A series of studies by Davis and coworkers link base deficit to resuscitation requirements and end-organ dysfunction, such as acute respiratory distress syndrome, renal failure, and coagulopathy. Cytokine and adhesion molecule changes also have been found to parallel changes in base deficit.¹³⁴⁻¹⁴⁰

Base deficit may vary with patient populations. Concern remains in older patients that base deficit is nonspecific and may reflect metabolic acidosis due to a variety of causes, including renal dysfunction and diabetes.^{116,117} Similar to temporal changes in lactate, base deficit variation over time may add to the value of this parameter.¹³² Patients with elevated base deficit also showed impaired oxygen use reflected in lower oxygen consumption. The timing of base deficit measurement also is important. One study suggested that the worst base deficit in the initial 24 hours was predictive of mortality rate along with blood pressure and estimated blood loss.¹³⁸ Some workers debate whether alcohol intoxication may worsen base deficit for similar levels of injury severity and hemodynamics after trauma. In a large database survey, use of alcohol did not change significant predictive value of admission lactate and base deficit.^{141,142} Resuscitation with normal saline (hyperchloremic metabolic acidosis) or lactated Ringer's solution (accumulation of D-lactate) may increase base deficit independent of injury severity. Acidosis associated with hyperchloremia is associated with lower mortality rate than that from other causes, particularly anaerobic metabolism.^{116,143} Base deficit levels and time to normalization of base deficit are similar to data for lactate in that correlation has been established with the need for resuscitation and risk of organ dysfunction and death after injury. Specific thresholds for outcome have not been determined, however, and there are no multicenter data that conclusively show that using base deficit as an end point for resuscitation improves survival.¹¹⁶

GASTRIC MUCOSAL pH

As systemic perfusion decreases, blood flow to vulnerable organs (brain and heart) is maintained at the expense of other organs (skin, muscle, kidneys, and intestines). Detection of subclinical ischemia to these organs may allow identification of patients requiring additional resuscitation despite normalized vital signs.^{116,144} Gastric tonometry is based on the finding that tissue ischemia leads to an increase in tissue partial pressure of carbon dioxide (PCO_2) and subsequent decrease in tissue pH. Because CO_2 diffuses readily across tissues and fluids, the PCO_2 of gastric secretions rapidly equilibrates with that in gastric mucosa. For elevation in gastric pH values to be accurate, it is important to withhold gastric feedings and suppress gastric acid secretion. To perform gastric tonometry, a semipermeable balloon is attached to a special nasogastric tube and placed in the stomach. The balloon is filled with saline, and CO_2 is allowed to diffuse into the balloon for a specific time. PCO_2 in the saline is then measured. Continuous CO_2 measuring electrodes are sometimes employed. Intramucosal pH is calculated from the Henderson-Hasselbalch equation. The difference between intragastric PCO_2 and arterial PCO_2 , or the intramucosal pH, correlates with the degree of gastric ischemia.¹⁴⁵

In studies of a small number of trauma patients, patients with low intramucosal pH (≤ 7.32) were more likely to develop complications or die.¹⁴⁶⁻¹⁴⁸ Patients with normal intramucosal pH fared well. Correlation to other parameters has not been rigorously studied. A larger trial examined the value of intramucosal pH and the gastric mucosal-arterial CO_2 gap (difference between intragastric PCO_2 and arterial PCO_2). Ability to predict multiple organ dysfunction and death was maximized with intramucosal pH less than 7.25 and CO_2 gap greater than 18 mm Hg. Similar to studies using blood lactate and base deficit, time course for changes in CO_2 gap or intramucosal pH may be important. Ivatury and associates^{149,150} compared changes in intramucosal pH with oxygen transport values. Although intramucosal pH changes paralleled improvement in oxygen transport, delay in achieving intramucosal pH was more predictive of organ system failure than oxygen transport parameters. The gap between gastric mucosal and arterial PCO_2 was similarly predictive. After resuscitation, changes in mucosal pH were an early predictor of complications.

Newer fiber-optic technologies increase the ease of gastric mucosal pH assessment.¹⁵¹ Although this parameter may be predictive of early resuscitation failure, accepted thresholds for failure and outcome data do not support widespread use to guide initial resuscitation after injury (Fig. 27.3).

NEAR-INFRARED SPECTROSCOPY

Measurement of skeletal muscle oxyhemoglobin levels by near-infrared spectroscopy offers a noninvasive measurement for evaluating adequacy of resuscitation from normalization of tissue oxygenation.^{116,117,145,152} This technology allows simultaneous measurement of tissue partial pressure of oxygen (PO_2), PCO_2 , and pH. In human volunteers, cerebral cortex and calf oxygen saturation as measured by near-infrared spectroscopy decreased in proportion to

Figure 27.3 Changes in oxygen transport parameters, biochemical indicators of resuscitation success, and local acid-base changes as reflected in gastric mucosal PCO_2 are described here. These collected data from McKinley and coworkers suggest the correlation between these common resuscitation parameters. Not all investigators or specific patient groups have complete correspondence among all resuscitation indices, however. (From McKinley BA, Valdivia A, Moore FA: Goal-oriented shock resuscitation for major torso trauma: What are we learning? *Curr Opin Crit Care* 2003;9:292-299.)

blood loss. Oxygenation index (oxygenated hemoglobin—deoxygenated hemoglobin) also decreased. Studies in injury suggest correlation of tissue oxygen saturation with systemic oxygen delivery, base deficit, lactate, and gastric mucosal PCO_2 .¹⁵³

This technology provides information regarding mitochondrial function. Normally, tissue oxyhemoglobin levels reflecting local oxygenation are tightly coupled to cytochrome function, reflecting mitochondrial oxygen

Box 27.2 Adrenal Insufficiency

Check adrenal function in patients who fail to respond to resuscitation.^{a-c} Adrenal insufficiency, a rare occurrence in the general population (<0.01%), is seen in 28% of seriously ill patients and 60% of severely injured trauma patients in contemporary series.^d Severe illness and stress activate the hypothalamic-pituitary-adrenal axis and stimulate the release of corticotropin (adrenocorticotrophic hormone) from the pituitary, which stimulates release of cortisol from the adrenal cortex. This action is an essential component of general adaptation to illness and contributes to maintenance of cellular and organ homeostasis.^{a-c}

Although a growing body of literature reviews adrenal insufficiency in critical illness with an emphasis on sepsis, we have seen a significant incidence of adrenal insufficiency, reflected by low serum cortisol levels, in severe injury with or without direct trauma to the brain.^{e,f} We suspect adrenal insufficiency in patients who are young and otherwise healthy and require vasoactive drugs in addition to large amounts of resuscitation fluid. Our approach to making the diagnosis of acute adrenal insufficiency is a spot cortisol level. Although a variety of treatment protocols for hormonal replacement exist, we provide 50 mg of hydrocortisone every 6 hours or 100 mg of hydrocortisone every 8 hours for 5 days. Consistent with the treatment threshold reported by Marik and Zaloga,^{b,f} we treat if a random cortisol concentration is less than 25 µg/dL. Severely injured patients have been reported to have random cortisol levels greater than 30 µg/dL.^d Although outcome data are unavailable to suggest the value of adrenal replacement in critically stressed young trauma patients, we have seen the effectiveness of this intervention repeatedly in our own practice.

consumption. In preliminary studies, when patients showed change in mitochondrial function, even in the absence of abnormality in systemic oxygen transport, multiple organ failure was more likely.¹⁵⁴ Nonetheless, at this time, work in this area is preliminary, and a role for this technology in management of traumatic shock has not been defined.

ADRENAL INSUFFICIENCY

Adrenal insufficiency is reviewed in [Box 27.2](#).

CLINICAL STRATEGIES

Clinical observations of shock in injury have been made for hundreds of years, but the optimal treatment continues to

be debated.¹¹⁵ Early observations are attributed to Paré, Le Dran, Latta, and Gross.^{155,156} Crile and Henderson were among the first to attribute the hemodynamic instability of shock to decreased intravascular volume and to propose therapy based on restoration of intravascular volume with administration of intravenous fluid.^{115,156} During the First World War, physiologists Cannon and Bayliss observed patients in clinical shock.⁶ These observers noted that patients with crush injuries despite absence of obvious blood loss also developed signs and symptoms of shock.^{157,158} Cannon later suggested the concept of deliberate hypotension in the treatment of wounds to the torso during war with the intent of minimizing internal bleeding until the time at which operative intervention could control the hemorrhage.^{159,160} In later studies, other authors reported laboratory models of ongoing arterial hemorrhage and concluded that regardless of the means used to increase blood pressure, either fluid resuscitation or vasopressor, bleeding would increase, with subsequent death.^{161,162}

Current guidelines for the treatment of hypotension secondary to hemorrhage after trauma recommend rapid infusion of crystalloid solutions to restore blood pressure.^{69,160} This premise is based in part on clinical studies and laboratory data showing that hemorrhagic shock in animals produced with controlled blood loss was reversible when blood loss was replaced with two to three times that volume of a crystalloid solution.¹⁶³⁻¹⁶⁵ Although controlled hemorrhage is a well-defined laboratory model, resuscitation of a patient with multiple injuries and active or uncontrolled bleeding may represent very different pathophysiology.¹¹⁵

In 1950, Wiggers¹⁶⁶ developed a standard hemorrhagic shock model in dogs. He and others showed that severe hypotension over several hours produced a condition in which infusion of withdrawn blood restored arterial pressure only temporarily.¹¹⁵ After intervals ranging from 30 minutes to 3 hours, arterial pressure declined again. Additional infusions of blood were followed by progressively poorer recovery and more rapid development of circulatory failure, ultimately resulting in the demise of the animal. This decompensation point in shock, defining a time at which reinfusion of shed blood could not resuscitate the animal, led to the concept of irreversible shock.¹⁶⁷ The approach to resuscitation of cellular, organ, and organism changes after hemorrhagic shock using the Wiggers model has been applied to all types of injury based in part on the elegant experiments of Shires and colleagues¹⁶³ and a series of other investigators.^{69,70}

EARLY LIMITED RESUSCITATION**ANIMAL STUDIES**

Several large animal studies explored the use of varying degrees of fluid resuscitation in animals receiving injuries leading to uncontrolled hemorrhagic shock. Bickell and coworkers¹⁶⁸ created infrarenal aortotomy using a stainless steel wire in 16 anesthetized Yorkshire swine weighing 23 to 40 kg, which had been instrumented with pulmonary artery and carotid artery catheters. When the wire was pulled, a 5-mm aortotomy with subsequent intraperitoneal hemorrhage followed. Animals were alternately assigned to an untreated control group or a treatment group receiving 80 mL/kg of lactated Ringer's solution as an intravenous

bolus. The volume of blood loss and mortality rate were significantly increased in animals treated with lactated Ringer's solution relative to the untreated control group. All control animals survived, whereas animals treated with lactated Ringer's solution died in less than 2 hours. Volume of hemorrhage identified in treated animals exceeded 2 L, whereas control animals lost on average less than 800 mL of blood.

Several observations may be made in relation to this widely cited report. First, mortality rate in the control group was low, leading one to question the severity of injury in the animal model. Second, fluid resuscitation administered, although consistent with replacement of two to three times the volume loss in blood with crystalloid, far exceeds standard resuscitation for a human patient of comparable weight. In addition, the rapidity of fluid administration may have served to diminish further any potential positive impact of fluid administration in this model of injury. The effect seen was reproduced, however, with other types of fluid administration in a comparable injury model. Other large animal studies of hypotensive resuscitation used graded resuscitation protocols.^{169,170}

Stern and coworkers¹⁶⁹ examined a swine model combining femoral artery hemorrhage via a catheter to a mean arterial pressure of 30 mm Hg with subsequent intra-abdominal aortic laceration producing a 4-mm tear and uncontrolled intraperitoneal hemorrhage. Three groups of animals were resuscitated to mean arterial pressures of 40 mm Hg, 60 mm Hg, and 80 mm Hg. No untreated control group was employed. Resuscitation was begun when the pulse pressure of each animal reached 5 mm Hg. Animals were resuscitated with saline at 6 mL/kg/minute to a maximum of 90 mL/kg, after which resuscitation fluid was changed to shed blood at 2 mL/kg/minute to a maximal volume of 24 mL/kg. Animals were observed for 60 minutes or until death. As noted previously, mortality rate was significantly higher in animals receiving the most aggressive resuscitation compared with less aggressively treated groups. Animals resuscitated most aggressively had higher volumes of intraperitoneal hemorrhage than the two other experimental groups. In addition, oxygen delivery, which was monitored in these animals, was significantly greater in the group resuscitated to a mean arterial pressure of 60 mm Hg than in the two other experimental groups. Similar observations were made in a second report from this same group in a study by Kowalenko and colleagues.¹⁷⁰

Clinical and preclinical studies focused on early limitation of crystalloid resuscitation and hemorrhagic shock focus on penetrating torso trauma but do not address initial care of patients with head injury, the leading cause of traumatic death in the United States. Historically, when shock accompanies head injury, the incidence of adverse outcome doubles. Because of the vulnerability of the injured brain to even brief periods of reduced perfusion, guidelines for the management of head injury state that delayed resuscitation cannot be considered applicable in head trauma.¹¹⁸ Nonetheless, in a large animal model using a standard cerebral injury along with uncontrolled hemorrhage secondary to aortotomy, there was no evidence of increased secondary cerebral ischemia with delayed resuscitation. Conventional resuscitation with lactated Ringer's solution resulted in signs of increased secondary brain injury.¹⁷¹

CLINICAL STUDIES

Martin and coworkers¹⁷² provided preliminary data in patients on the effect of aggressive versus delayed prehospital resuscitation of uncontrolled hemorrhagic shock after penetrating injury. These workers evaluated the effect of delaying fluid resuscitation until surgical intervention could control the source of hemorrhage on outcome of hypotensive trauma victims. Injury severity was similar in standard resuscitation and delayed resuscitation groups. The rate of survival to hospital discharge was 69% in the delayed resuscitation group and 56% in the standard resuscitation group. The difference between these groups did not reach statistical significance owing to small sample size.

Much attention has been directed to resuscitation of patients after injury after a report from Bickell and associates¹⁷³ that appeared in the *New England Journal of Medicine*. The authors reported a prospective clinical trial of adults with penetrating truncal trauma who were hypotensive in the field as indicated by a systolic blood pressure less than 90 mm Hg. Patients were randomly assigned to placement of intravascular catheters with standard prehospital and trauma center fluid resuscitation using lactated Ringer's solution or an experimental group in which vascular catheters were placed but intravenous fluids were not administered until patients reached the operating room. Patients were excluded from this trial if they were noted to have a field revised trauma score of zero consistent with cardiopulmonary arrest or had sustained fatal gunshot wounds to the head with neurologic injury that precluded long-term survival.²⁸ In addition, patients with penetrating truncal injury who did not require operation were excluded. After 1069 patients were screened during the 37 months of this study, 598 patients were enrolled—309 in an immediate resuscitation group receiving standard fluids according to Advanced Trauma Life Support protocols and 289 in a delayed resuscitation group, which did not receive intravenous fluids until reaching the operating room.⁶⁹

The immediate and delayed resuscitation groups were well matched with respect to age, gender, and anatomic injury as measured by the ISS, Revised Trauma Score (physiologic response to injury), and systolic blood pressure.^{174,175} Field response times for prehospital providers in this trial were short, averaging 30 minutes or less. The trauma center interval (i.e., the interval in the hospital before operation) was surprisingly long—44 minutes in the immediate resuscitation group and 52 minutes on average in the group receiving delayed resuscitation. Prehospital fluid administration averaged less than 900 mL in the immediate resuscitation group versus less than 100 mL in the delayed resuscitation cohort. Fluid administration in the trauma center before operation averaged greater than 1600 mL of fluid in the immediate resuscitation group, whereas the delayed resuscitation patients averaged 283 mL of fluid received. Operative blood loss between the study groups was not different. Among the 289 patients who received delayed fluid resuscitation, 203 (70%) survived and were discharged from the hospital. Of the 309 patients who received immediate fluid resuscitation, 193 (62%) survived ($P = 0.04$). Patients in the delayed resuscitation group displayed a trend toward reduced postoperative complications, including acute respiratory distress syndrome, sepsis syndrome, acute

renal failure, coagulopathy, wound infection, and pneumonia, compared with patients in the immediate resuscitation group ($P = 0.08$).

A subgroup analysis from this study was reported at a subsequent meeting of the American Association for the Surgery of Trauma. When Wall and coworkers¹⁷⁶ examined major subgroups in the patient population reported by Bickell and colleagues, a statistical difference in hospital survival could be shown only in patients who had sustained penetrating cardiac injury.¹¹⁵ Patients with major vascular injury, solid organ injury requiring operation, or noncardiac thoracic injury had comparable survival in the immediate and delayed resuscitation groups.

Although these early clinical studies represent a remarkable accomplishment in design, organization, and data analysis, many questions remain unanswered. None of the studies reported was blinded, and a randomization scheme was not employed. In the trial of Bickell and colleagues, in which the difference in mortality rate rested in a difference in survival of a small number of patients in the experimental groups, 22 patients in the delayed resuscitation group were given intravenous fluids in violation of study design.¹⁷³ Although these individuals were appropriately included in an intent-to-treat analysis, the impact of selected fluid administration on study outcome is unclear. The authors also have been criticized for excluding patients *after* randomization because of injuries considered too minor (no operative therapy) or too severe (revised trauma score of zero). Exclusion of these patients may invalidate the statistical approach employed and increase the difficulty of the clinician seeking guidance from this work. Finally, time spent in the trauma center by these hypotensive patients with injuries requiring operation was surprisingly long. Although the resuscitation groups described differed statistically in vital signs and hematologic parameters, it is unclear whether the differences observed had clinical significance.

We await additional data on the military approach to resuscitation, which requires innovation and effectiveness in austere environments.¹⁷⁷ Contemporary recommendations include limitation of fluid administration unless systolic blood pressure is less than 80 to 85 mm Hg or is rapidly falling. Another clinical indicator for fluid resuscitation is decreasing mentation without evidence of head injury. Key assessment parameters are mental status and the presence of a radial pulse. In many settings, no fluids are administered in the presence of a strong radial pulse and normal mentation. Pulse deterioration or decreasing level of consciousness are indicators for intervention. When fluids are given, a number of small-volume colloids with high tonicity or colloids in combination with hypertonic saline are being investigated. Even early hospital resuscitation is designed to emphasize the use of blood products and minimize crystalloids and nonblood colloids in the setting of major injury.

CLINICAL PATHWAY—EARLY RESUSCITATION

In all of the preclinical and clinical work described, the mechanism of injury and survival remains unclear. Among considerations are the impact of fluid resuscitation on

early clot formation in the setting of uncontrolled hemorrhage.^{115,169} Other workers suggest that rapidity in resuscitation of pulse pressure may relate to mechanical disruption of initial thrombus.¹⁶⁹ Fluid resuscitation may contribute to dilution of clotting factors in the setting of exaggerated bleeding in uncontrolled hemorrhage.^{115,160} The data to support these observations are limited. Coagulopathy proportional to volume of injured tissue and severity of shock may be seen even before resuscitation fluids are provided.¹¹

Despite provocative preclinical and clinical data, there is insufficient evidence to propose practice guidelines or make recommendations. “Uncontrolled” hemorrhage itself remains undefined. This problem is best seen as injury with blood loss occurring in the absence of surgical or mechanical hemostasis or the “control” provided by regulated blood removal through a vascular cannula. It is unclear whether a vascular injury after a torso gunshot wound and a shattered spleen after an automobile crash are different in this regard. The bottom-line message from all of the studies is that elevation of the blood pressure to normal or supranormal levels results in resumption of bleeding from the uncontrolled site, and rebleeding leads to recurrent shock and death of the experimental animal. Other work shows that animals subjected to shock could be successfully resuscitated at lower than “normal” mean arterial pressures if the bleeding site was controlled as part of the resuscitation program. Shock victims resuscitated with electrolyte solutions are subject to progressive hemodilution, and this may lead to death. The lessons that clinicians should learn from this body of data are as follows.^{69,115,145,11}

1. Operation to control bleeding is part of resuscitation.
2. Blood pressure levels are convenient but possibly misleading end points for shock resuscitation in that resuscitation to normal or supranormal pressures may be harmful if the effort delays operation to control bleeding or the pressure elevation causes rebleeding. Better end points (e.g., tissue oxygenation or other metabolic parameters) are needed.
3. Blood loss is increased in the setting of significant soft tissue insults combined with shock. Early administration of blood products should stimulate use of a balanced administration strategy with PRBCs, FFP, and platelets given in equal proportions.
4. Resuscitation of traumatic shock, similar to fluid management of a burned patient, requires repeated observation, judgment, and skill and cannot be accomplished by recipe or formula.

The clinical trials that have sought to extend the previously described experimental concepts into the realm of patient care have dealt primarily with blood loss secondary to penetrating injury because this clinical condition is as close a simulation to a pure hemorrhage model as is available in clinical medicine. It is useful to emphasize that multiple blunt injury, multiple wounds, and extensive soft tissue trauma are not similar to pure hemorrhage models in that occult blood and fluid losses and other inflammatory factors exist that make the quantitation of injury severity difficult.

MANAGEMENT OF TRAUMATIC SHOCK IN THE INTENSIVE CARE UNIT

Before admission to the ICU, resuscitation is directed at maintaining blood pressure and reducing heart rate through volume loading with crystalloid and blood products. Relatively simple clinical end points are employed.⁶⁹ *This approach should be adequate for 95% of injured patients.* On admission to the ICU, severely injured patients may receive a central venous catheter or a pulmonary artery catheter to monitor hemodynamics and refine further the direction of resuscitation.¹⁷⁸ A series of early reports by Shoemaker and coworkers proposed that supranormal oxygen delivery (600 mL/minute/m²) and resuscitation to a plateau oxygen consumption were appropriate clinical end points. Although observations of improved hemodynamic response in survivors of injury make intuitive sense, driving injured patients to supranormal hemodynamic performance was not associated with improvement in clinical outcome.^{116,122-125} Reduced goals for oxygen delivery (500 mL/minute/m²) are proposed among end points for support of patients receiving pulmonary artery catheter monitoring.¹⁷⁹⁻¹⁸¹

In a series of studies characterizing resuscitation of injured patients in the ICU, Moore and coworkers used the pulmonary artery catheter to describe response to fluid administration. Criteria identifying patients considered for placement of a pulmonary artery catheter and need for ICU resuscitation include major injury (two or more abdominal organs, two or more long bone fractures, complex pelvic fractures, flail chest, or major vascular injury), blood loss (anticipated need for >6 units PRBC during the first 12 hours after hospitalization), and metabolic stress (arterial

base deficit > 6 mEq/L during the first 12 hours after hospital admission). A trauma victim older than 65 years with any two of the previous criteria also warrants consideration for pulmonary artery catheter insertion and ICU resuscitation. Patients with these criteria who also incurred severe brain injury, defined as Glasgow Coma Scale score less than or equal to 8 in the trauma ICU and abnormality on brain computed tomography scan, were not resuscitated by protocol during development of this approach unless assessed by the attending neurosurgeon to be at low risk of secondary brain injury with these procedures.^{180,181} In my practice, I find that the brain, similar to other organs, benefits from aggressive resuscitation (Table 27.3).

A sequential approach to shock resuscitation using a pulmonary artery catheter is advocated by Moore with McKinley and coworkers.^{178,179} This approach includes a series of interventions including administration of PRBC and lactated Ringer's solution to optimize cardiac index and pulmonary capillary wedge pressure as described in a classic Starling curve. Milrinone, dobutamine, and norepinephrine are used as vasoactive agents as necessary to provide mean arterial pressure greater than 65 mm Hg and oxygen delivery index greater than 500 mL/minute/m². These patients require large volumes of protocol-directed shock resuscitation (approximately 15 L for oxygen delivery index >500 mL/minute/m²). Significant urine output volumes also should be expected. This large net positive balance suggests unrecognized ongoing blood loss or extreme fluid shifts between intravascular, interstitial, and intracellular compartments, or both, for severely injured patients (Fig. 27.4).

The protocol-driven approach described has provided a variety of observations.¹⁸² First, even elderly patients respond

Table 27.3 Summary of Protocol for Resuscitation of Shock Resulting from Major Torso Trauma*

Intervention	Threshold	Method
Transfuse (PRBC)	DO ₂ I <500 mL/min/m ² ; hemoglobin <10 g/dL (age ≥65 years, <12 g/dL)	1 g hemoglobin/dL/unit PRBC; bolus transfusion; then hemoglobin analysis (bedside); then calculate DO ₂ I
Volume load (LR)	DO ₂ I <500 mL/min/m ² ; hemoglobin ≥10 g/dL (age ≥65 years, ≥12 g/dL); PCWP <15 mm Hg (age ≥65 years, <12 mm Hg)	1-L LR bolus infusion (age ≥65 years, 0.5 L); then measure PCWP; then calculate DO ₂ I
Starling curve (NS)	DO ₂ I <500 mL/min/m ² ; hemoglobin ≥10 g/dL (age ≥65 years, ≥12 g/dL); PCWP ≥15 mm Hg (age ≥65 years, ≥12 mm Hg)	0.5- or 0.25-L NS bolus infusion; then measure PCWP and CI; CI-PCWP optimal if ΔCI ≤-0.3; ΔPCWP ≤+4 with two consecutive boluses; then calculate DO ₂ I
Inotrope	DO ₂ I <500 mL/min/m ² ; hemoglobin 10 g/dL (age ≥65 years, ≥12 g/dL); CI and PCWP optimized	Milrinone, 0.1-μg increments to 0.8 μg/kg/min, or dobutamine, 2.5-μg increments to 20 μg/kg/min; calculate DO ₂ I
Vasopressor	DO ₂ I <500 mL/min/m ² ; MAP <65 mm Hg	Norepinephrine, 0.05-μg increments to 0.2 μg/kg/min; measure MAP; calculate DO ₂ I

*Details of the resuscitation protocol used by McKinley and coworkers are given. Selected drugs for inotropic and vasopressor support are listed. Patients also are treated to age-appropriate hemoglobin levels and given fluid infusion based on a volume loading protocol until filling pressures and DO₂I are optimized.

CI, cardiac index; CWP, capillary wedge pressure; DO₂I, oxygen delivery index; LR, lactated Ringer's solution; MAP, mean arterial pressure; NS, normal saline; PCWP, pulmonary capillary wedge pressure; PRBC, packed red blood cells.

Modified from McKinley BA, Kozar RA, Cocanour CS, et al: Normal versus supranormal oxygen delivery goals in shock resuscitation: The response is the same. J Trauma 2002;53:825-832.

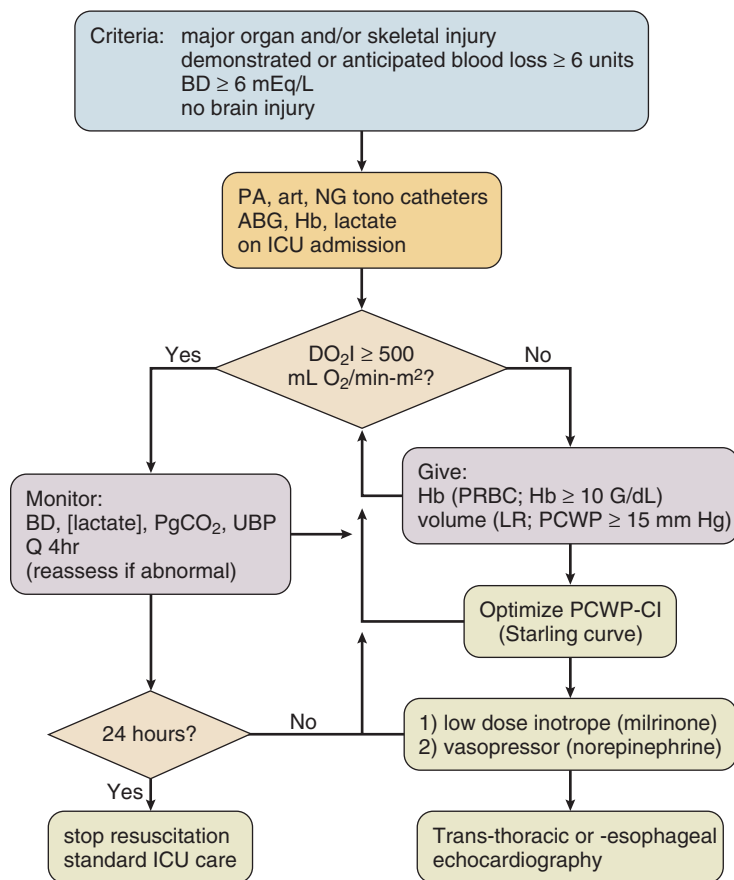

Figure 27.4 A few patients require additional aggressive resuscitation in the ICU. Frequently, these patients require insertion of a pulmonary artery catheter. This protocol is the most widely reported strategy for crystalloid and blood administration in stabilization of these patients coming from a series of articles published by McKinley, Moore, and associates. ABG, arterial blood gas; BD, base deficit; CI, cardiac index; DO₂I, oxygen delivery index; Hb, hemoglobin; ICU, intensive care unit; LR, lactated Ringer's solution; NG, nasogastric; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; PgCO₂, transgastric oxygen; UBP, urinary bladder pressure. (From Marr AB, Moore FA, Sailors RM, et al: Preload optimization using "Starling curve" generation during shock resuscitation: Can it be done? *Shock* 2004;21:300-305.)

to ICU resuscitation after injury.¹⁸⁰ In general, the maximal oxygen delivery response is less than that of younger patients, and elderly patients have a greater requirement for inotropic support.¹⁸³ Second, a Starling curve generation approach is feasible and reliably improves hemodynamic resuscitation from major trauma. Supranormal resuscitation is neither necessary nor desirable in the management of patients with trauma associated with shock.¹⁷⁸ Third, aggressive resuscitation, particularly in the setting of ongoing bleeding, increases the risk of elevated intra-abdominal pressure and abdominal compartment syndrome.¹⁸⁴ Preload-driven resuscitation may cause bowel edema with subsequent venous obstruction, declining cardiac output, decreased urinary output, and compromise of systemic oxygenation. Finally, although many end points for interventions for goal-directed resuscitation in critical injury exist, systemic oxygen transport is the current state of the art in the most severely injured patients and is the basis for future development of clinical processes for resuscitation of shock caused by major trauma (Fig. 27.5).¹⁸²

The utility of the pulmonary artery catheter in the management of patients with severe injury is suggested by a study using data obtained in the National Trauma Data Bank.¹⁸⁵ From more than 450,000 records, 53,000 patients were reviewed. These patients were admitted between January 1994 and December 2001. Patients survived more than 48 hours and underwent at least one diagnostic or therapeutic procedure. The patients were 16 to 90 years old and distinguished by ISS and initial base deficit. Approximately 2000 patients who had insertion of a pulmonary artery catheter

during hospitalization were compared with 51,000 patients who did not. Logistic regression analysis was used to develop a model that examined mortality rate after injury. Factors included in the model were use of a pulmonary artery catheter, age, emergency department base deficit, ISS, comorbid conditions, mechanism of injury, and specific injury patterns as identified by the Abbreviated Injury Scale. Overall, patients managed with a pulmonary artery catheter were older and had a higher ISS, greater emergency department base deficit, and higher mortality rates (29.7% with pulmonary artery catheter versus 9.8% without pulmonary artery catheter). Patients with spine, abdominal, chest, or head injury and patients with at least one Abbreviated Injury Scale score equal to or greater than 3 were more likely to be managed with a pulmonary artery catheter.

Pulmonary artery catheter use was associated with increased mortality rate in all subgroups of ISS, emergency department base deficit, and age. As age, base deficit, and ISS increased, however, the risk of death associated with pulmonary artery catheter use decreased, and an apparent benefit of pulmonary artery catheter use emerged. In contrast, less severely injured trauma patients (ISS 16 to 24) and severely injured patients without high admission base deficit (>5) had increased mortality rate associated with pulmonary artery catheter placement regardless of age.

Although these observations come from a large database, retrospective study design and subgroup analysis are not optimal for definitive hypothesis testing. Finally, neither timing of placement for pulmonary artery catheters nor cause of death and specific relationship to placement of the

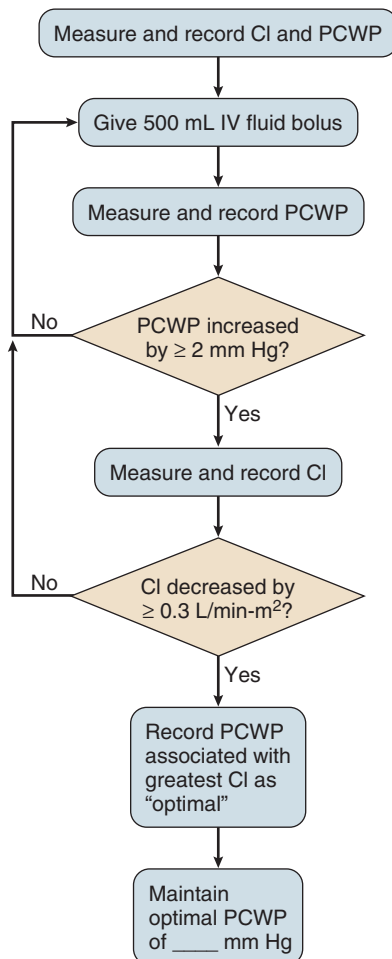

Figure 27.5 This simple algorithm describes a Starling curve protocol for optimization of filling pressures as a part of resuscitation of severely injured patients in the critical care unit where a pulmonary artery catheter is employed. CI, cardiac index; PCWP, pulmonary capillary wedge pressure. (From Marr AB, Moore FA, Sailors RM, et al: Preload optimization using “Starling curve” generation during shock resuscitation: Can it be done? *Shock* 2004;21:300-305.)

pulmonary artery catheter could be conclusively examined by analysis of the National Trauma Data Bank. Nonetheless, these data suggest that injured patients may derive benefit from pulmonary artery catheter-guided resuscitation to avert complications related to persistent perfusion deficits. Further focused examination of patients with risk factors for poor outcome is warranted.¹⁸⁵

MASSIVE TRANSFUSION

Independent of mechanism of injury, hemorrhagic shock consistently is the second leading cause of early death among injured patients, with only CNS injury consistently more lethal.¹⁸⁶ Primary CNS injury is devastating and has a high rate of prehospital mortality; prevention is the best strategy.¹⁸⁷ Hemorrhagic shock accounts for 30% to 40% of trauma deaths and is more amenable to interventions to reduce mortality and morbidity rates.¹⁸⁶ In addition, approximately 25% of CNS injuries are complicated by hemorrhagic shock.^{188,189} Hemorrhage contributes to death during

the prehospital period in 33% to 56% of cases, and exsanguination is the most common cause of death among individuals found dead on arrival of emergency medical services personnel.⁴⁷ Hemorrhage accounts for the largest proportion of mortality rates occurring within the first hour of trauma center care and greater than 80% of operating room deaths after major trauma.^{186,190} Although the need for massive transfusion (defined as administration of ≥ 10 units of PRBC in <24 hours) is probably necessary in only 3% of patients in busy trauma centers, this intervention can be lifesaving, and preliminary data suggest that early aggressive administration of blood products reduces morbidity and mortality rate and decreases overall product use.¹⁹¹

Numerous general observations can be made.¹⁹¹⁻¹⁹³ Most patients receiving massive transfusion are treated initially with crystalloid fluids followed by non-cross-matched type O red blood cells. Plasma therapy is typically delayed while waiting for blood typing and plasma to thaw. Platelets frequently are not given until patients have multiple units of PRBCs. Coagulopathy is common and difficult to correct. Plasma and platelets are inadequately used and greater emphasis is needed on plasma and platelet administration.

A typical massive transfusion protocol begins in the emergency department when the senior trauma practitioner orders transfusion of O-negative PRBC and invokes an organization-specific massive transfusion protocol.^{193,194} This is followed by administration of 4 to 6 additional typed or O-negative units of PRBC and a similar number of units of FFP and platelets. Therapy continues with containers sent from the blood bank, each containing red blood cells, plasma, and platelets. Goals are normalization of the PT and elevation of the platelet count to 50 to $100 \times 10^9/L$. The fibrinogen level is checked after 6 to 12 units of PRBC, and cryoprecipitate is given if the fibrinogen level is less than 1 g/L. This triggers administration of 10 units of cryoprecipitate. Once a common component of massive transfusion strategies, recombinant activated factor VII has been deemphasized in both military and civilian practice.¹⁹⁵⁻¹⁹⁸

Major trauma centers have developed transfusion protocols to address rapid blood loss and trauma-associated coagulopathy. This strategy has demonstrated improved survival in severely injured trauma patients. Although many centers have implemented massive transfusion protocols, a standardized initiation policy has not been defined. Frequently, activation of massive transfusion protocols is provider dependent and variability exists among high-volume centers.

A number of scoring systems have been developed to rapidly predict the patient requiring massive transfusion.¹⁹⁹⁻²⁰¹ Of these scores, the ABC (assessment of blood consumption) score, which incorporates penetrating mechanism of injury, positive ultrasound examination of the abdomen in the emergency department, arrival systolic blood pressure of 90 mm Hg or less, and arrival heart rate of 120 beats/minute or more, has been reported and validated in large patient sets. Although multiple more sophisticated criteria have been proposed, having an ABC score of two criteria or greater correctly classified the patient requiring massive transfusion in up to 85% of cases. Other investigators point out that hypotension and evidence of coagulopathy are the strongest predictors of massive transfusion. Additional data from military and civilian practice is awaited to bring further clarity to appropriate transfusion triggers.

TRANEXAMIC ACID

Tranexamic acid is a derivative of amino acid lysine that inhibits fibrinolysis by blocking binding sites on plasminogen. This agent has been used in a variety of surgical trials and has been demonstrated to reduce blood transfusion requirement. The massive CRASH-2 study, incorporating over 20,000 patients, evaluates tranexamic acid as a means to address fibrinolysis occurring as a component of coagulopathy after trauma.^{202,203} CRASH-2 was conducted in over 250 hospitals and 40 countries. Over 20,000 patients with significant bleeding or at risk for significant bleeding were assigned within 8 hours of injury to either tranexamic acid or matching placebo. All-cause mortality rate was significantly reduced with tranexamic acid. Specific risk of death due to bleeding was also significantly reduced. This remarkable outcome was accomplished without a significant increase in thrombotic events. Subsequent analysis of the CRASH-2 data, however, reveals that greatest efficacy came when treatment was initiated within 3 hours after injury. In fact, treatment after 3 hours seemed to increase the risk of death due to bleeding. A recent review of military experience with tranexamic acid, the MATTERS trial, also demonstrates improved outcomes with early administration of this inexpensive drug shortly after injury. This military experience with tranexamic acid suggests improvement in outcome in patients receiving as little as 1 unit of PRBCs. Incremental risk with administration of tranexamic acid was not demonstrated.²⁰⁴

The role for tranexamic acid in trauma systems where massive transfusion protocols incorporate FFP containing all indigenous antifibrinolytic elements in plasma remains unclear. In developed trauma systems, the best place for tranexamic acid may actually be in the prehospital environment as this material can readily be maintained in helicopter and road transport programs. Prehospital administration of blood products, especially plasma, is uncommon in civilian settings; thus, tranexamic acid offers an early opportunity to manage coagulopathy.²⁰⁵ Opportunities for use of this promising material in the critical care setting are being defined.

RISKS OF EARLY RED BLOOD CELL TRANSFUSION

Blood transfusion in trauma has been identified as an independent predictor of multiple organ failure, systemic inflammatory response syndrome, increased postinjury infection, and increased mortality rate in multiple studies.²⁰⁶ Cumulative risks have been related to the number of units of PRBC transfused, increased storage time of transfused blood, and possibly the presence of leukocytes in donor blood. Many authors have concluded that blood transfusion in an injured patient should be minimized whenever possible.²⁰⁷

Large single-institution data sets examined the impact of blood transfusion in postinjury multiple organ failure.^{136,208,209} Variables identified as early independent predictors of multiple organ failure included age older than 55 years, ISS equal to or greater than 25, and greater than 6 units of PRBC in the first 12 hours after admission. Base deficit greater than 8 mEq/L in the first 12 hours and lactate greater than 2.5 mol/L also were independent predictors

of multiple organ failure. Subsequent prospective work confirmed the importance of blood transfusion as an independent risk factor for postinjury multiple organ failure after controlling for other indices of shock, including base deficit and lactate. Additional studies of blood product use after injury associate blood transfusion with increased mortality rate. Potential confounding shock variables, including base deficit, serum lactate, age, gender, race, Glasgow Coma Scale score, and ISS, were controlled in this analysis.

Factors contributing to complications associated with red blood cell transfusion include storage time, increased endothelial adherence of stored red blood cells, nitric oxide binding by free hemoglobin in stored blood, donor leukocytes, host inflammatory response, and reduced red blood cell deformability.^{205,210} Nonetheless, transfusion of an injured patient with balanced blood component therapy is the only option for treatment of severe hemorrhagic shock. Although other hemoglobin-based oxygen carriers hold great promise and ultimately may provide better outcomes for injured patients, these materials have not come to be used. In an effort to minimize adverse events, attempts to minimize the use of blood transfusion in injury are appropriate outside major hemorrhage.

SPECIAL PROBLEMS

ABDOMINAL COMPARTMENT SYNDROME

A compartment syndrome is a condition in which increased pressure within a confined anatomic space adversely affects function and viability of tissues contained within. Confined anatomic spaces associated with compartment syndromes are fascial spaces of the extremities, the globe as in glaucoma, and the cranial cavity as in epidural or subdural hematoma. Abdominal compartment syndrome is a condition in which sustained pressure within the abdominal wall, pelvis, diaphragm, and retroperitoneum adversely affects the function of the gastrointestinal tract and related extra-peritoneal organs. Abdominal compartment syndrome is receiving increasing recognition as a complication of massive resuscitation after trauma, burns, or other surgical procedures (Box 27.3). Operative decompression is frequently required. Pressures around 5 to 7 mm Hg in the peritoneal cavity are normal. Short-duration pressure increases frequently occur with coughing, Valsalva maneuvers, defecation, and weightlifting. Intra-abdominal pressure can be nonpathologically increased in obese individuals. Elevated intra-abdominal pressure is a common finding among critically ill medical and surgical patients.²¹¹⁻²¹³

A more recent consensus conference on abdominal compartment syndrome has created improved definitions in relation to abdominal compartment syndrome (Table 27.4). For standardization, intra-abdominal pressure should be expressed in mm Hg and measured at end expiration with the patient supine after ensuring that abdominal muscle contractions are absent. The transducer is zeroed at the midaxillary line. The current reference standard for intra-abdominal pressure measurement is pressure measured via an indwelling urinary drainage catheter within the bladder. The recommended technique for measuring intra-abdominal pressure is to clamp the urinary catheter and

Box 27.3 Risk Factors for Intra-abdominal Hypertension and Abdominal Compartment Syndrome

Acidosis (pH < 7.2)
 Hypothermia (core temperature < 33°C)
 Polytransfusion (>10 units packed red blood cells/24 hours)
 Coagulopathy (platelets < 55,000/mm³ or activated partial thromboplastin time 2× normal or higher or prothrombin time < 50% or international standardized ratio > 1.5)
 Sepsis (American-European Consensus Conference definitions)
 Bacteremia
 Intra-abdominal infection or abscess
 Peritonitis
 Liver dysfunction or cirrhosis with ascites
 Mechanical ventilation
 Use of positive end-expiratory pressure (PEEP) or the presence of auto-PEEP
 Pneumonia
 Abdominal surgery, especially with tight fascial closures
 Massive fluid resuscitation (>5 L colloid or crystalloid/24 hours)
 Gastroparesis, gastric distention, or ileus
 Volvulus
 Hemoperitoneum or pneumoperitoneum
 Major burns
 Major trauma
 High body mass index (>30)
 Intra-abdominal or retroperitoneal tumors
 Prone positioning
 Massive incisional hernia repair
 Acute pancreatitis
 Distended abdomen
 Damage control laparotomy
 Laparoscopy with excessive inflation pressures
 Peritoneal dialysis

From Malbrain ML, Cheatham ML, Kirkpatrick A, et al: Results from the International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome, I: Definitions. *Intensive Care Med* 2006;32:1722-1732.

instill a maximal volume of 25 mL of sterile, room-temperature saline into the bladder with the patient in the supine position. After zeroing a transducer and a stabilization period of at least 30 to 60 seconds, the mean intra-abdominal pressure can be read on a bedside monitor or as the height of the fluid column in urinary drainage tubing.

Intra-abdominal hypertension is defined by a sustained or repeated intra-abdominal pressure greater than 12 mm Hg or an abdominal perfusion pressure less than 60 mm Hg, where abdominal perfusion pressure = mean arterial pressure – intra-abdominal pressure. Abdominal compartment syndrome is present when organ dysfunction occurs as a result of intra-abdominal hypertension. Abdominal compartment syndrome is further defined by sustained or repeated intra-abdominal pressure greater than 20 mm Hg or abdominal perfusion pressure less than 60 mm Hg in association with new-onset single or multiple organ system failure. In contrast to intra-abdominal hypertension,

Table 27.4 Consensus Definitions List

Definition 1	IAP is the steady-state pressure concealed within the abdominal cavity.
Definition 2	APP = MAP – IAP.
Definition 3	FG = GFP – PTP = MAP – 2 × IAP.
Definition 4	IAP should be expressed in mm Hg and measured at end expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the midaxillary line.
Definition 5	The reference standard for intermittent IAP measurement is via the bladder with a maximal instillation volume of 25 mL sterile saline.
Definition 6	Normal IAP is approximately 5-7 mm Hg in critically ill adults.
Definition 7	IAH is defined by a sustained or repeated pathologic elevation in IAP ≥12 mm Hg.
Definition 8	IAH is graded as follows: grade I, IAH 12-15 mm Hg; grade II, IAP 16-20 mm Hg; grade III, IAP 21-25 mm Hg; grade IV, IAP > 25 mm Hg.
Definition 9	ACS is defined as a sustained IAP >20 mm Hg (with or without an APP <60 mm Hg) that is associated with new organ dysfunction/failure.
Definition 10	Primary ACS is a condition associated with injury or disease in the abdominopelvic region that frequently requires early surgical or interventional radiologic intervention.
Definition 11	Secondary ACS refers to conditions that do not originate from the abdominopelvic region.
Definition 12	Recurrent ACS refers to the condition in which ACS redevelops after previous surgical or medical treatment of primary or secondary ACS.

ACS, abdominal compartment syndrome; APP, abdominal perfusion pressure; FG, filtration gradient; GFP, glomerular filtration pressure; IAH, intra-abdominal hypertension; IAP, intra-abdominal pressure; MAP, mean arterial pressure; PTP, proximal tubular pressure.

From Malbrain ML, Cheatham ML, Kirkpatrick A, et al: Results from the International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome, I: Definitions. *Intensive Care Med* 2006;32:1722-1732.

abdominal compartment syndrome is not graded but rather considered as an “all or none” phenomenon.^{213,214}

Intra-abdominal hypertension has a variety of physiologic effects. In experimental preparations, animals die as a result of congestive heart failure as abdominal pressure passes a critical threshold. Increased intra-abdominal pressure decreases cardiac output and left and right ventricular stroke work, while increasing central venous pressure, pulmonary artery wedge pressure, and systemic and pulmonary vascular resistance. Abdominal decompression reverses these changes. As both hemidiaphragms are displaced upward with increased intra-abdominal pressure, decreased

thoracic volume and compliance are seen. Decreased volume within the pleural cavity causes atelectasis and decreases alveolar clearance. Pulmonary infections also may result. Ventilated patients with abdominal hypertension require increased airway pressure to deliver a fixed tidal volume. As the diaphragm protrudes into the pleural cavity, intrathoracic pressure increases with reduction in cardiac output and increased pulmonary vascular resistance. Ventilation and perfusion abnormalities result, and blood gas measurements show hypoxemia, hypercarbia, and acidosis.²¹⁵

Elevation in intra-abdominal pressure also causes renal dysfunction. Inadequate renal perfusion pressure and renal filtration gradient have been proposed as critical factors in the development of renal insufficiency associated with elevated intra-abdominal pressure. The filtration gradient is the mechanical force across the glomerulus and equals the difference between glomerular filtration pressure and proximal tubular pressure. In the presence of intra-abdominal hypertension, proximal tubular pressure may be assumed to equal intra-abdominal pressure. Glomerular filtration pressure may be estimated as mean arterial pressure minus intra-abdominal pressure. Changes in intra-abdominal pressure may have a greater impact on renal function and urine production than changes in mean arterial pressure. Oliguria is thought to be one of the first signs of intra-abdominal hypertension. Control of intra-abdominal pressure leads to reversal of renal impairment. Oliguria may be seen with intra-abdominal pressure of 15 to 20 mm Hg. Deterioration in cardiac output plays a role in diminished renal perfusion, but even with maintenance of cardiac output, impairment of renal function persists in intra-abdominal hypertension.^{211,216-218}

Other organs affected by increased intra-abdominal pressure include the liver, where hepatic blood flow has been shown to decrease with abdominal hypertension.^{219,220} It may be assumed that hepatic synthesis of acute-phase proteins, immunoglobulins, and other factors of host defense may be impaired by reduced hepatic blood flow. Other gastrointestinal functions may be compromised by increased intra-abdominal pressure. Splanchnic hypoperfusion may begin with an intra-abdominal pressure of 15 mm Hg. Reduced perfusion may create changes in mucosal pH, translocation, bowel motility, and production of gastrointestinal hormones. Finally, intracranial hypertension is seen with chronically increased intra-abdominal pressure. Intracranial hypertension has been shown to decrease when intra-abdominal pressure is reduced in morbidly obese patients and in intracranial injury.

Operative decompression is the method of choice for treatment of patients with intra-abdominal hypertension and associated evidence of organ dysfunction. After decompression, improvements in hemodynamics, pulmonary function, tissue perfusion, and renal function have been shown in a variety of clinical settings. To prevent hemodynamic decompensation during decompression, intravascular volume should be restored, oxygen delivery should be normalized, and hypothermia and coagulation defects should be corrected. The abdomen should be opened in patients with adequate venous access and controlled ventilation. Adjunctive measures to combat reperfusion washout from by-products of anaerobic metabolism include acute use of vasoconstrictor agents to avoid sudden changes in

blood pressure. After decompression of the abdomen, the fascial gap is left open using one of a variety of temporary abdominal closure methods.

In a recent report, Cheatham and Safcsak review their experience with percutaneous, ultrasound-guided drainage of ascitic fluid contributing to abdominal hypertension and abdominal compartment syndrome.^{221,222} These investigators suggest that in patients with significant fluid accumulation creating abdominal hypertension, percutaneous drainage can avoid the need for decompressive laparotomy with its associated morbidity and occasional complications. Additional reports from other centers are required. To date, apart from the large experience described previously, percutaneous control of fluid accumulation to manage abdominal hypertension and compartment syndrome is limited to case reports.

EXTREMITY COMPARTMENT SYNDROME

The numerous causes of extremity compartment syndrome include complications of open and closed fractures, arterial injury, temporary vascular occlusion, snakebite, drug abuse, burns, physical exertion, and gunshot wounds. The most common cause of compartment syndrome is muscle injury leading to edema, which is correlated to the amount of tissue damage. Pressure is increased within the closed fascial space first by intracellular swelling followed by hematoma formation if a fracture is present. Because extremities, particularly at the calf, are composed of relatively unyielding fascial compartments, circulatory compromise occurs as tissue pressure increases with resulting ischemia and tissue damage. Leakage of intracellular fluid follows, and a further increase in intracompartmental pressure is seen.²²³

When extremity injuries produce complete ischemia, skeletal muscle that is deprived of oxygen may survive for 4 hours without irreversible damage. Total ischemia of 8 hours' duration produces irreversible change. Peripheral nerves conduct for 1 hour after onset of total ischemia and can survive for 4 hours with only neurapraxic damage. After 8 hours, axonotmesis and irreversible damage occur. Ischemia caused by reduction or cessation of blood flow occurs when the perfusion gradient to a muscle compartment falls below a critical level. Perfusion is related to the compartment pressure. When intracompartmental blood pressure is 25 mm Hg, tissue perfusion in injured tissues is substantially decreased.²²³⁻²²⁵

Fasciotomy should be performed when intracompartmental pressure approaches 25 mm Hg, or if an extremity has been completely ischemic for 6 hours, the patient's clinical condition is worsening, substantial tissue injury is present, or tissue pressure is increasing.²²⁵ Prophylactic treatment is valuable because fasciotomy does not reverse changes caused by initial extremity injury but can prevent changes resulting from secondary ischemic insults.

Pain, pallor, paralysis, paresthesias, and pulselessness are the classic hallmarks of extremity compartment syndrome. If treatment is not initiated until all of these signs are present, poor results are obtained. Pain and aggravation of pain by passive stretching of the muscles in the involved compartment is the most sensitive clinical finding. Assessment of pain is useful when patients are conscious and can respond cognitively to examination. In unconscious patients

at risk for compartment syndrome, tissue pressure measurements may be the only objective criteria for diagnosis. Measurement of compartment pressures is obtained in all extremity compartments at risk and proximal and distal to any fractures. The highest pressure noted should serve as the basis for determining the need for fasciotomy.

PELVIC FRACTURES

Substantial blunt force is required to disrupt the pelvic ring. The extent of injury is related to the direction and magnitude of force applied. Associated abdominal, thoracic, and head injuries are common. Force applied to the pelvis can cause rotational displacement with opening or compression of the pelvic ring. Other types of displacement seen with pelvic fractures are vertical with complete disruption of the ring and the posterior sacroiliac complex.²²⁶

Patients with pelvic ring injuries are easily divided into two groups on the basis of clinical presentation—patients who are hemodynamically stable and patients who are hemodynamically unstable.²²⁶ There is a dramatic difference in mortality rates between pelvic fracture patients who are hypotensive and patients who are hemodynamically stable. Hemodynamic stability and biomechanical pelvic instability are separate though related issues, which tends to confuse the clinical picture. The source of bleeding may be multifactorial and not directly related to the pelvic fracture itself. Blood loss secondary to pelvic fracture that contributes to hemodynamic instability is a significant risk factor, however. Early fracture diagnosis and stabilization using external skeletal fixation are crucial in the acute phase of patient management.²²⁷ Treatment of the patient also is directed by response to initial fluid resuscitation. Retroperitoneal bleeding in a pelvic fracture usually arises from a low-pressure source—the cancellous bone at the fracture site or adjacent venous injury. Significant retroperitoneal arterial bleeding occurs in approximately 10% of patients. Clinical evidence has suggested that provisional fracture stabilization using external fixation devices or even wrapping the fractured pelvis in a bed sheet can control low-pressure venous bleeding. Continued, unexplained bleeding after provisional fracture stabilization suggests an arterial source. Angiography with embolization of the involved vessel is indicated. Therapeutic angiography also may be required after abdominal exploration if a rapidly expanding or pulsatile retroperitoneal hematoma is encountered.²²⁸

KEY POINTS

- Shock after trauma is not the same as simple hemorrhage. Blood loss is combined with an inflammatory component.
- Because of inflammation associated with hemorrhage, the rate and amount of resuscitation are increased

KEY POINTS (Continued)

- after injury compared with hemorrhage outside the setting of trauma.
- The classic neuroendocrine response leading to conservation of salt and water in traumatic shock can be linked to neuroimmune feedback loops, which modulate inflammatory response.
- Although flaws in present crystalloid resuscitation preparations exist, a clear benefit of routinely available colloids has not been shown.
- A variety of metabolic and oxygen transport end points for resuscitation have been identified. In general, these end points change in a consistent fashion after injury. None of the available resuscitation end points is sufficient to limit or guide therapy after injury at this time.
- Resuscitation to supranormal oxygen transport parameters does not improve outcome after injury. A staged approach using a pulmonary artery catheter, which should be necessary in less than 5% of injured patients, may be helpful.
- Although massive transfusion reduces overall blood product requirements in patients with rapid blood loss, limited resuscitation and blood product conservation are seen as appropriate in many injured patients.

PROPHYLAXIS AND IMMUNOTHERAPY

The term *anaphylaxis* refers to a life-threatening event, allergic in nature, which may result from IgE- or non-IgE-mediated mast cell degranulation. The clinical manifestations of severe anaphylaxis are often explosive in onset and may lead to upper airway obstruction, respiratory failure, and circulatory shock. Milder symptoms can also develop. The term *anaphylactoid reaction*, which referred to a non-IgE-mediated reaction, is no longer being used. A recent National Institutes of Health (NIH) consensus conference defined anaphylaxis as one of the following three scenarios.¹

1. Acute onset of a reaction (minutes to hours) with involvement of the skin, mucosal tissue, or both *and at least one of the following*: (a) respiratory compromise (b) or reduced blood pressure or symptoms of end-organ dysfunction;
2. Two or more of the following that occur rapidly after exposure to a *likely* allergen for that patient—involvement of the skin/mucosal tissue, respiratory compromise, reduced blood pressure or associated symptoms, and persistent gastrointestinal symptoms; or
3. Reduced blood pressure after exposure to a *known* allergen (adapted from Sampson and colleagues¹).

The IgE-mediated anaphylactic response is classified as a type I reaction according to the Gell and Coombs classification. The IgE-mediated anaphylactic reaction has clinical features similar to other, milder type I reactions, such as allergic rhinitis, hives, urticaria, and allergic asthma. IgE-mediated anaphylactic reactions are characterized by a well-defined immunologic sequence of events that involves antigen-specific and IgE-specific effector cells. When stimulated, these cells release a variety of inflammatory

mediators.² The effector cells consist of mast cells and basophils, which are based primarily in tissues and in the circulating blood volume. Severe anaphylaxis rapidly progresses to a generalized systemic reaction. Agents that produce well-documented IgE-mediated anaphylactic reactions include medications such as beta lactam antibiotics, biologic agents, nonsteroidal anti-inflammatory drugs (NSAIDs), foods (peanut and other legumes, nuts from trees [walnuts, almonds, etc.], milk, and egg), Hymenoptera venoms (honey bees, yellow jackets, hornets, wasps, and fire ants), natural rubber latex, occupational allergens, and seminal fluid prostate-specific antigen (Table 28.1).

Immune-mediated IgE-dependent or IgE-independent and non-immune-mediated mast cell degranulation-mediated anaphylactic reactions have similar clinical features. Agents capable of producing direct mast cell degranulation include NSAIDs, opiates, ciprofloxacin, and physical factors, (cold, heat, exercise). Patients who are taking beta blockers or ACE inhibitors may develop severe anaphylaxis to an inciting agent and are less likely to respond to first-line agents.³⁻⁶

In idiopathic anaphylaxis, the pathophysiology and triggering events are unknown. Idiopathic anaphylaxis is a diagnosis of exclusion. It is mostly seen in adults and adolescents. About half these patients have concomitant atopic disease. They respond to treatment with corticosteroids and antihistamines.^{7,8} Special testing like serum tryptase, C4 levels may be necessary to exclude conditions such as systemic mastocytosis, hereditary angioedema, and acquired C1 inhibitor deficiency.

Factitious anaphylaxis is a type of Munchausen syndrome. Patients with this disorder typically have an acute crisis that resembles anaphylaxis because of intentional self-exposure

Table 28.1 Agents Frequently Associated with Immune and Nonimmune Types of Anaphylaxis

Category	Examples
Antibiotics	Penicillin and penicillin analogues, β -lactam antibiotics, cephalosporins, tetracyclines, erythromycin
Nonsteroidal anti-inflammatory drugs	Salicylates, ibuprofen, indomethacin
Narcotic analgesics	Morphine, codeine, meprobamate
Local anesthetics	Procaine, lidocaine, cocaine
General anesthetics	Thiopental
Muscle relaxants	Suxamethonium, tubocurarine, pancuronium
Blood products and antisera	Red blood cell, white blood cell, and platelet transfusions; gamma globulin; rabies, tetanus, diphtheria antitoxin; snake and spider antivenom
Diagnostic agents	Iodinated radiocontrast agents
Foods	Eggs, milk, nuts, legumes (peanuts, soybeans, kidney beans), fish, shellfish
Venoms	Bees, wasps, hornets, fire ants, scorpions, snakes
Enzymes and other biologic agents	Acetylcysteine, pancreatic enzyme supplements, chymopapain
Extracts of potential allergens used in desensitization	Pollen, food, venom extracts
Chemotherapeutic agents	Cisplatin, cyclophosphamide, daunorubicin, methotrexate
Insulin	Pork, beef, and human insulin
Other drugs	Protamine, chlorpropamide, parenteral iron, iodides, thiazide diuretics

to an allergen. These reactions may be attributed to an unknown allergen or a well-defined allergen such as bee venom.

Anaphylaxis may progress to shock, multiple organ failure, and death. Early recognition and rapid implementation of treatment is lifesaving. It is essential that patients with anaphylaxis be accurately diagnosed so that management can proceed as quickly as possible. Because these severe reactions may continue despite appropriate treatment, and because a recurrence of symptoms after an initial favorable response may occur, patients with severe life-threatening anaphylaxis should be admitted to the hospital or intensive care unit (ICU) for continued monitoring.

HISTORY AND INCIDENCE

Allergic emergencies have been described in humans since ancient times.⁹⁻¹¹ At the turn of the twentieth century, a more detailed description of these events was reported by two French physiologists, Portier and Richet.¹² They coined the term anaphylaxis, which originates from the French word *anaphylactique*, which means “reverse protection.” It was believed that these reactions were in contrast to the attenuated or tachyphylactic reactions that commonly protect subjects from reintroduced antigens such as viruses. More recent research defining the role of IgE; the interactions between IgE, antigen, mast cells, basophils, and eosinophils; and the biochemical mediators from these cells has clarified the events leading to clinical anaphylaxis.^{2,13-15}

The true incidence of the various types of anaphylactic reactions is difficult to determine because these reactions are often spontaneous and unpredictable and are clinically similar to other acute reactions. Lifetime prevalence of anaphylaxis due to all triggers is estimated to be 0.05% to 2%.¹⁶ Estimates of the incidence of the most commonly reported episodes are possible, however. In the United States, penicillin alone probably accounts for several hundred fatalities

each year.¹⁷⁻¹⁹ Anaphylaxis to the cephalosporins also is commonly reported.²⁰ It has been estimated that among patients with an allergic reaction to a penicillin, there is a 3% to 7% rate of allergic reaction to a cephalosporin. Reports of anaphylactic reactions to the newer β -lactam antibiotics are accumulating.²¹

Insects, especially those of the Hymenoptera order, which includes bees, wasps, hornets, and fire ants, account for numerous immediate hypersensitivity reactions. About 3% of adults and 1% of children are affected and the anaphylaxis can be fatal at the first sting. About 50 people experience fatal reactions to insect stings every year in the United States, and about half of them do not have a prior sting exposure.²²⁻²⁴ Fire ants are aggressive insects from South America that now reside in the southern United States. In some areas, they have been known to sting 58% of the residents yearly and account for serious allergic reactions.²⁵

Snake bites account for probably a dozen or so anaphylactic deaths per year in the United States. Snake bites may be associated with typical anaphylactic symptoms and other problems related to the enzymes, proteins, and peptides in venom. Local tissue necrosis, coagulation problems, hemolysis, and neurologic transmission defects have been described. In the United States, most anaphylactic reactions to snake bites are caused by pit vipers. These snakes include rattlesnakes, water moccasins, and copperheads.^{26,27}

Food-induced anaphylaxis is probably the most common cause of anaphylaxis and accounts for 30% of fatalities. Peanuts (legumes) and typical nuts from trees account for 90% of fatal cases. Additional common food antigens include fish, soybeans, egg whites, and shellfish.²⁸ Biphasic reactions are much more common in food-induced anaphylaxis than in other types of anaphylaxis and have been reported in 25% of fatal cases.^{29,31}

Iodinated contrast agents account for approximately 125 deaths per year³² and lead to clinical symptoms similar to anaphylaxis. Life-threatening reactions are extremely rare, with an incidence of 0.1%.^{33,34} With the advent of low

osmolar iodinated contrast agents, the risk of anaphylaxis to contrast agents has decreased drastically.³⁵

Latex, used in surgical gloves, balloons, condoms, rubber bands, and many other products, may produce anaphylaxis.^{36,37} The use of universal precautions as a result of the acquired immunodeficiency syndrome epidemic has increased the number of reactions to latex in health care workers. Children with spina bifida and genitourinary tract abnormalities are especially susceptible to latex-induced anaphylaxis because of frequent exposure to latex-containing bladder catheters and other products.

Anaphylactic reactions during anesthesia have been described and typically are associated with hypotension and cardiopulmonary arrest. One review suggests that most cases of intraoperative anaphylaxis are from muscle relaxants (e.g., suxamethonium, tubocurarine, pancuronium).³⁸ Latex, protamine, and blood products also may cause intraoperative anaphylaxis.

Anaphylaxis and other types of IgE-mediated allergic reactions tend to occur in susceptible, genetically predisposed individuals. The reason for the genetic inheritance of sensitivity to the antigens that produce anaphylaxis continues to be speculative. A popular theory is that type I reactions, when confined to an area of parasitic invasion (e.g., intestinal tract), facilitate the killing and removal of parasites and confer a survival advantage to individuals capable of mounting a type I response. Various clinical and laboratory observations support this view.³⁹⁻⁴¹ The sites of IgE synthesis in laboratory subjects correspond to the sites of entry of many parasites. These sites include the lymphoid tissue of the respiratory tract, the gastrointestinal tract, and the skin. Eosinophils, cells that migrate to the site of antigen introduction in anaphylaxis, elaborate mediators that are toxic to the outer parasitic covering.

When type I reactions to antigen are no longer restricted to local areas because of genetically determined or acquired factors, the release of mediators becomes generalized. Problems typical of a systemic response include increased microvascular permeability, loss of intravascular volume, abnormal vascular reactivity (especially vasodilation), and impaired pulmonary gas exchange. Local IgE-mediated

reactions become decompensatory when systemic involvement ensues.

PATHOGENESIS AND PATHOPHYSIOLOGY

IMMUNOLOGIC MECHANISMS LEADING TO MAST CELL AND BASOPHIL ACTIVATION AND MEDIATOR RELEASE

When an antigen to which an individual has previously been sensitized is reintroduced, a sequence of events is initiated that leads to mediator release (Fig. 28.1). At least several weeks are required between the initial exposure to antigen and a subsequent exposure for clinical manifestations of anaphylaxis to occur. The antigen may be introduced through the skin, respiratory tract, or gastrointestinal tract. Antigen also may be introduced intravenously, usually in association with drug administration. Although most venoms are injected subcutaneously, some may access the circulation through an intravascular route.

In most cases of anaphylaxis, when antigen is reintroduced into the host, it encounters IgE, previously synthesized by plasma cells in response to a previous introduction of antigen. IgE, similar to other immunoglobulins, is composed of two heavy chains and two light chains linked by disulfide bonds. Two portions of the molecule have well-defined functions. The Fab portion of the molecule recognizes and binds antigen. The Fc portion of the molecule binds reversibly to receptors on the surface of mast cells and basophils (Fig. 28.2).

The combination of reintroduced antigen with antigen-specific IgE sets the stage for a sequence of biochemical and cellular events that produce the clinical syndrome of anaphylaxis. The bivalent antigen cross-bridges two IgE molecules (see Fig. 28.1). Cross-bridging facilitates the approximation of Fc surface receptors on mast cells and basophils, triggering the release of mediators from intracellular granules and membrane-based phospholipids. The systemic release of these mediators leads to the pathophysiologic

Figure 28.1 The sequence of events leading to mediator release starts with sensitization (initial introduction of a bivalent antigen) and synthesis of antigen-specific IgE. IgE then reversibly binds to mast cells or basophils. When antigen is reintroduced, two cell-bound IgE molecules are linked by the bivalent antigen in a process called *cross-linking*. Cross-linking facilitates the approximation of Fc surface receptors on the mast cell and basophil and initiates a sequence of intracellular biochemical reactions that culminate in mediator release. ECF-A, eosinophil chemotactic factor of anaphylaxis; NCF, neutrophil chemotactic factor; PAF, platelet-activating factor; PGs, prostaglandins; SRS-A, slow-reacting substance of anaphylaxis.

Figure 28.2 In immune-mediated IgE-dependent anaphylaxis, each molecule consists of four polypeptide chains. Two are heavy chains (epsilon [ε]) and are unique to the IgE class of immunoglobulins. Light chains are either kappa (κ) or lambda (λ) chains and may be found in other types of immunoglobulins.

changes that produce the clinical manifestations of anaphylaxis.

Clinical reactions similar to anaphylaxis mediated by immunoglobulins of the IgG class have been described. IgG molecules may combine with antigens, producing an antigen-antibody complex that activates complement. Activation of complement generates C3a and C5a, also known as *anaphylatoxins* because they stimulate mediator release from mast cells and basophils. IgG-mediated reactions are considered type III reactions according to the classification of Gell and Coombs or may be referred to as *Arthus* reactions. These reactions may characterize IgA-deficient individuals who exhibit sudden reactions to blood transfusions. These individuals may develop an antibody of the IgG class to the IgA in the transfused blood product.^{42,43} This combination of IgG and IgA antibody activates complement, generates C3a and C5a, and produces a sudden reaction typical of anaphylaxis. Because approximately 1 in 700 individuals is IgA deficient, numerous people are susceptible to this type of blood transfusion reaction.⁴³ The anaphylactic responses to protamine may be IgG-, IgE-, or non-immune-mediated.⁴⁴⁻⁴⁶

NONIMMUNOLOGIC EVENTS LEADING TO MEDIATOR RELEASE

The mediators released during nonimmune reactions originate from mast cells and basophils and are identical to the mediators of immune-mediated anaphylaxis. The direct activation of surface receptors on mast cells and basophils by antigen may be responsible for mediator release in these reactions. Iodinated contrast agents, opiates, and highly charged polyionic antibiotics seem to activate surface receptors directly. Physical stimuli, including heat, cold, and hyperosmolar stimuli, also are capable of stimulating mast cells and basophils. Exercise-induced anaphylaxis may be associated with the stimulation of mast cells through cooling of the airways. Other possible mechanisms include complement activation without immune complex mediation (old preparations of propafol with cremophor diluent),⁴⁷ direct mast cell degranulation (merperidine),⁴⁸ and direct activation of the kinin-kallikrein pathway, resulting in the

generation of bradykinin, C3a, and C5a (oversulfated chondroitin sulfate in heparin products).⁴⁹

CELLULAR CHARACTERISTICS OF ANAPHYLAXIS

Despite the release of similar mediators during anaphylaxis, mast cells and basophils differ in several ways. Mast cells are more abundant than basophils and generally reside in the connective tissue of subcutaneous and submucosal areas. Basophils characteristically circulate in the blood.⁵⁰ Despite these differences in location and number, functional differences between the two cell types have not been clearly identified. Both types of cells have receptors for the Fc portion of IgE, and both have granules that bind basic dyes. In addition, the granules of both cells contain histamine and various other mediators that participate in the anaphylactic response.

Eosinophils are commonly identified in the tissues and plasma of patients with both immune- and non-immune-mediated anaphylactic reactions. These cells typically migrate to the site of antigen introduction. They are attracted by a variety of chemotactic factors, including factors derived from mast cells and basophils, antigen-antibody complexes, histamine, and complement. The granules of eosinophils stain with acidophilic dyes and contain a variety of biochemical mediators that are toxic to helminthic parasites. Substances that inactivate leukotrienes and histamines also are elaborated. Eosinophils function as modulators of the inflammatory response triggered by mast cell and basophil activation.^{51,52}

Platelets and polymorphonuclear leukocytes also may be involved in the anaphylactic response. These cells respond to mast cell-derived and basophil-derived chemotactic factors and to tissue injury. They release a variety of mediators that may be responsible for recurrent and late-phase reactions (see the following discussion).

BIOCHEMICAL MEDIATORS OF ANAPHYLAXIS

The biochemical mediators of anaphylaxis are divided into *primary* and *secondary* mediators. Mediators directly released from mast cells and basophils are termed *primary mediators* (Table 28.2). Secondary mediators are released from other cell types in response to primary mediator release (Table 28.3). Primary mediators are subdivided further into *preformed* and *newly synthesized* mediators. Preformed mediators are formed and stored in the intracellular granules of mast cells and basophils. Newly synthesized mediators are derived from the metabolism of arachidonic acid, a phospholipid derived from cell membrane.

Histamine is a well-characterized primary mediator stored and released from the granules of mast cells and basophils. Histamine stimulates H₁ and H₂ receptors located on the surfaces of vascular and bronchial smooth muscle cells. Stimulation of H₁ receptors leads to precapillary arteriolar dilation, contraction of postcapillary venules, and formation of intracellular gaps between capillary endothelial cells. By increasing capillary hydrostatic pressure and permeability, these changes initiate the movement of plasma into the interstitial space. In the lung, H₁ receptor stimulation is associated with bronchial smooth muscle contraction. H₂ receptor stimulation leads to vasodilation, enhanced mucus

Table 28.2 Physiologic Effects of Primary Mediators of Anaphylaxis Derived from Mast Cells and Basophils

Mediator(s)	Physiologic Effect(s)
Histamine	
H ₁ -receptor stimulation	Bronchial smooth muscle contraction Increased vascular permeability Cardiac arrhythmias Increased mucus secretion Vasoactive effects (vasodilation, vasoconstriction)
H ₂ -receptor stimulation	Increased vascular permeability Increased mucus and gastric acid secretion Activation of inhibitory lymphocytes
H ₃ -receptor stimulation	Inhibition of histamine synthesis and release
Platelet-activating factor	Increased vascular permeability Bronchospasm Aggregation and activation of platelets Attraction of neutrophils and eosinophils
Eosinophil chemotactic factors	Attraction of eosinophils
Neutrophil chemotactic factors	Attraction of neutrophils
Arachidonic acid metabolites	
Prostaglandin D ₂	Bronchoconstriction Potentiates leukocyte migration
Prostaglandin E ₂	Bronchodilation
Prostaglandin F ₂	Bronchoconstriction
Leukotriene C ₄ , leukotriene D ₄ , leukotriene E ₄	Bronchoconstriction Increased vascular permeability Attraction of neutrophils and eosinophils
Leukotriene B ₄	
Enzymes	
Hydrolytic enzymes	Degradation of parasitic and host tissue
Proteases	Degradation of parasitic and host tissue Interaction with complement components, coagulation cascade, and kinin system
Tryptase	Generation of complement anaphylatoxins, inhibition of fibrinogen
Carboxypeptidase	Deactivation of complement anaphylatoxins
Oxidative enzymes	
Superoxide dismutase	Inactivation of oxygen and associated cytotoxic effects
Peroxidase	Inactivation of cytotoxic effects of hydrogen peroxide
Heparin	Anticoagulant activity May assist in the repair of injured tissues
Adenosine	Bronchospasm
Serotonin	Regulates mast cell degranulation Vasoactive effects

Table 28.3 Secondary Mediators of Anaphylaxis and Physiologic Effects

Mediator(s)	Physiologic Effect(s)
Neutrophil, platelet, and eosinophil-derived mediators	Permeability, coagulation changes, proteolysis
Activated complement system	
C3a and C5a	Contract bronchial smooth muscle; increase vascular permeability; attract neutrophils, macrophages, and monocytes
C6-C9	Membrane damage
Activated coagulation cascade	Intravascular coagulation, permeability changes, tissue injury
Activated kinin system (bradykinin)	Increases vascular permeability

secretion, increased heart rate and myocardial contractility, increased gastric acid secretion, and inhibition of T cells. The vasoactive and cardiac effects of H₂ receptor stimulation primarily contribute to the clinical manifestations of anaphylaxis.

The family of arachidonic acid metabolites known as *leukotrienes* consists of newly synthesized primary mediators that function as potent vascular permeability agents and bronchoconstrictors. Arachidonic acid metabolism via the cyclooxygenase pathways produces prostaglandins with bronchoconstrictive effects—prostaglandin D₂ and prostaglandin F₂. Other mediators that are released are tryptase, carboxypeptidases, and proteoglycans.

The primary mediator release from mast cells and basophils sets the stage for involvement by secondary mediators. Secondary mediators include products of enzyme-dependent cascading biochemical pathways. In addition, secondary mediators may be derived from other involved cells, such as neutrophils, platelets, and eosinophils.

BIOCHEMICAL AND PHARMACOLOGIC REGULATION OF MEDIATOR RELEASE

The biochemical regulation of mediator release provides a rationale for the pharmacologic therapy of anaphylaxis. The release of primary mediators is thought to be modified by intracellular levels of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) and calcium and other bivalent cations. Pharmacologic agents that affect the intracellular levels of these modulators and inhibit mediator release are often used in the treatment of anaphylaxis (Box 28.1).

β_2 -Adrenergic agonists increase intracellular levels of cAMP by activating adenylate cyclase. This increase in cAMP subsequently inhibits the release of mediators. The methylxanthines aminophylline and theophylline also increase cAMP levels through the inhibition of phosphodiesterase. Because cGMP antagonizes the action of cAMP, agents that decrease cGMP inhibit mediator release. Anticholinergic drugs decrease cGMP levels and may have a role in the treatment of anaphylaxis.

Mediator release from mast cells and basophils is associated with an influx of calcium. Although calcium blocking agents theoretically may be useful in the treatment of anaphylaxis, clinical experience with use of these agents for this condition is lacking. Conversely, calcium administration may be harmful in anaphylaxis because of its association with enhanced mediator release. Other bivalent cations, such as magnesium and manganese, also enhance mediator release. Multiple tyrosine kinases are activated and regulate by exerting either stimulatory or inhibitory actions on the signal transduction cascade.⁵³⁻⁵⁵ Sphingosine-1-phosphate has been identified recently as one of the mediators that serves as a modulator in the mast cell. In addition, it is now labeled as a circulating mediator in anaphylaxis.⁵⁶

Box 28.1 Intracellular Regulation of Mediator Release by Pharmacologic Agents

Inhibit Release

By increasing cAMP

β -Adrenergic drugs (e.g., epinephrine)
Phosphodiesterase inhibitors (e.g., aminophylline, theophylline)

By decreasing cGMP

Anticholinergic drugs (e.g., ipratropium)

Enhance Release

By decreasing cAMP

β -Adrenergic blocking agents
 α -Adrenergic drugs

By increasing cGMP

Cholinergic drugs

cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate.

PATHOPHYSIOLOGIC EFFECTS OF MEDIATORS

The numerous mediators released during anaphylactic crisis have many physiologic effects that have been studied extensively in the laboratory. Although it is difficult to determine the specific actions of each mediator in anaphylaxis, the cumulative effects of mediator release have been described in the clinical setting. These effects include abnormalities secondary to increased vascular permeability; vascular resistance changes, primarily vasodilation; and bronchospasm. Autopsies of fatal cases of anaphylaxis reveal edema of the lungs, upper airway (including the larynx and epiglottis), skin, and viscera. Pulmonary congestion is typical in fatal anaphylaxis, and light microscopy often reveals fluid-filled pulmonary alveoli.⁵⁷ In another series of fatal cases of anaphylaxis, acute pulmonary emphysema was observed in almost half of cases.⁵⁸ This condition is characterized by hyperextended alveoli and thinning of the alveolar septum. Because of the association of acute pulmonary emphysema with laryngeal edema, these fatalities were thought to be caused by upper airway obstruction, with alveolar rupture resulting from forced exhalation against the obstruction.

Cardiac abnormalities, including arrhythmias, reduced contractility, and myocardial ischemia, have been described in anaphylaxis but seem to be uncommon.⁵⁹ These abnormalities may be secondary to the effects of histamine and other mediators on the myocardium. Other contributing factors include circulatory shock, hypotension, increased adrenergic tone, and drugs used to treat anaphylaxis.

LATE-PHASE OR BIPHASIC REACTIONS

Both immune-mediated and non-immune-mediated anaphylactic reactions may be followed by late-phase reactions (also termed *biphasic reactions*). These reactions typically occur 6 to 12 hours after the initial reaction as a result of the migration of mast cells, basophils, and polymorphonuclear leukocytes into areas of antigen introduction. A secondary wave of mediator release and recurrence of symptoms may be observed.⁶⁰⁻⁶²

CLINICAL AND HEMODYNAMIC FEATURES

The constellation of clinical signs and symptoms in anaphylaxis may vary widely for individuals; however, severe, rapidly progressive symptoms after exposure to antigen are characteristic. The portal of entry for the antigen, the rate of absorption, and the degree of hypersensitivity to the antigen also influence the clinical presentation. Current research is focusing on the role of genetic factors as well. Gastrointestinal symptoms, including nausea, vomiting, abdominal cramps, and diarrhea, may precede more generalized clinical manifestations after ingestion of an antigen. Inhalation of an antigen may be associated with nasal coryza, a sensation of tightness or a lump in the throat, hoarseness, stridor, wheezing, and dyspnea. Introduction of antigen through the skin may produce local pruritus, urticaria, and swelling before progression to systemic symptoms.

The most life-threatening reactions are usually explosive in nature, often occurring within minutes of exposure to

the antigen. Victims of these reactions have been noted to describe a feeling of impending doom before more defined symptoms develop. Generalized cutaneous abnormalities include erythema, urticaria, and flushing. Swelling of the periorbital and perioral areas is characteristic. Upper and lower airway abnormalities are common and especially dangerous. Swelling of the posterior pharynx, uvula, tonsils, and vocal cords may develop rapidly. Auscultation of the chest may reveal generalized wheezing and prolongation of expiration. Auscultatory and radiographic signs of pulmonary edema are characteristic of severe episodes. Signs of circulatory shock include hypotension, oliguria, and lactic acidosis from intravascular volume depletion. In some instances, such as the intravenous injection of venom or a drug, circulatory shock may develop without preceding cutaneous and respiratory abnormalities. The clinical features of anaphylaxis may respond quickly to treatment or, in the most severe cases, may last for several hours to several days. An initial favorable response to treatment may be followed by a late-phase reaction—a recurrence of symptoms resulting from a second wave of mediator release approximately 6 to 12 hours after the initial reaction.^{60,62}

Hemodynamic descriptions of human anaphylaxis are limited to detailed studies of a few cases. The loss of circulating plasma volume is characteristic and is associated with hemoconcentration, hypotension, tachycardia, decreased cardiac filling pressures, and decreased cardiac output.^{63,64} Vasodilation, associated with a decrease in systemic vascular resistance, may contribute to the reduction in venous return and cardiac output. When oxygen delivery decreases to levels below systemic oxygen demands, anaerobic metabolic pathways are activated, and lactic acidosis emerges.⁶⁵ Decreases in myocardial contractility seem to be minimal in studies of human anaphylaxis using routine hemodynamic monitoring. This is supported by the observation that most patients with anaphylaxis respond favorably to fluid therapy and do not require inotropic support.⁶³⁻⁶⁷ In a few case reports, reduced myocardial contractility has been observed in association with myocardial ischemia and infarction.⁶⁸⁻⁷³ Some of these adverse cardiac effects have been associated with epinephrine administration, but in some cases they also have been noted before pharmacologic treatment.⁶⁸⁻⁷³

Laboratory studies provide more detailed descriptions of the hemodynamic features of anaphylaxis. After antigenic challenge in primates, a transient increase in cardiac output is observed and is followed by decreases in arterial pressure, right and left ventricular filling pressures, and peripheral vascular resistance.⁷⁴ The transient increase in cardiac output has been attributed to vasodilation-induced left ventricular unloading or an increase in cardiac contractility or both. Elevated plasma levels of epinephrine, norepinephrine, and histamine have been shown in laboratory animals and humans and may contribute to this increase in contractility.^{75,76} Cardiac output eventually decreases when hypotension and shock become established. In human and canine models of anaphylaxis, a reduction in venous return has been observed secondary to vasodilation and pooling of blood in the splanchnic circulation.⁷⁷⁻⁷⁹ Loss of plasma volume from increased vascular permeability is probably a contributing factor.

When pulmonary edema fluid is sufficiently copious to be sampled from the airway of patients with anaphylaxis,

albumin concentrations and oncotic pressures are nearly identical to plasma values. These findings and the association of pulmonary edema with low pulmonary artery wedge pressures suggest that the pulmonary edema in anaphylaxis is noncardiogenic and secondary to increased microvascular permeability.⁶³ Although transient pulmonary hypertension and increased pulmonary vascular resistance have been observed in primates immediately after antigen challenge,⁷⁴ it is unknown whether pulmonary hypertension characterizes human anaphylaxis.

Hemodynamic characteristics of human anaphylaxis are determined by generalized vasodilation and increased vascular permeability, which lead to venous pooling of blood and loss of circulating plasma volume. Permeability edema develops in the lung. Changes in cardiac contractility are not typical of human anaphylaxis; however, reduced contractility may characterize patients who exhibit signs of myocardial ischemia or infarction, especially in association with epinephrine therapy.

MANAGEMENT

INITIAL MANAGEMENT

The initial assessment of a patient with suspected anaphylaxis should be brief and specific because immediate therapeutic interventions are required. Because a variety of conditions may appear similar to anaphylaxis (Box 28.2), it is important to rule out these events quickly. Vasovagal episodes are among the most common conditions confused with anaphylaxis. Bradycardia, pale skin, and diaphoresis in an acutely ill patient are suggestive of a vasovagal attack, in contrast to the tachycardic, flushed appearance typical of anaphylaxis.

When it is strongly suspected that the patient is experiencing a severe or potentially severe anaphylactic episode, the following steps should proceed rapidly (Fig. 28.3): (1) assurance of a patent airway, (2) removal of toxin at the site of introduction or an attempt to delay the systemic absorption of toxin or both, (3) establishment of intravenous access for fluid therapy, and (4) initiation of pharmacologic support with epinephrine (Box 28.3). A team approach is

Box 28.2 Conditions That Mimic Anaphylaxis

- Vasovagal episodes
- Acute pulmonary events
 - Acute asthmatic attacks
 - Acute pulmonary edema
 - Pulmonary embolus
 - Spontaneous pneumothorax
 - Foreign body aspiration
- Acute cardiac events
 - Supraventricular tachycardias
 - Acute myocardial infarction/ischemia
- Drug overdoses
- Insulin shock
- Carcinoid attacks

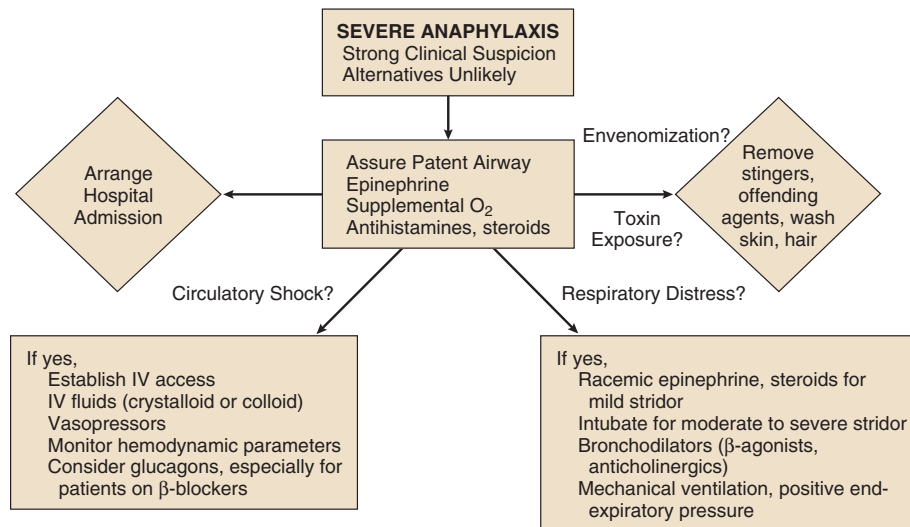

Figure 28.3 Overview of the clinical management of severe anaphylaxis.

essential in severe cases of anaphylaxis because assessment and interventions must proceed rapidly and, if possible, simultaneously.

Admission to the hospital is required for all patients experiencing severe anaphylaxis. Hospital personnel should have advanced airway skills and be capable of managing hemodynamic instability. Although symptom recurrence is uncommon in patients who respond favorably to treatment,⁷⁹ hospital admission and monitoring is recommended for all patients with severe anaphylaxis because of the potential for late-phase reactions, which may be severe and may occur 12 hours after the initial attack. While in the hospital, the patient should be monitored for signs of circulatory shock, respiratory failure, and upper airway obstruction. Blood pressure, urine output, and heart and respiratory rate require frequent evaluation.

The electrocardiogram should be monitored continuously during the acute period because anaphylaxis has been associated with serious arrhythmias and cardiac ischemia. In addition, drugs used to treat anaphylaxis and circulatory shock may precipitate cardiac problems. When signs of circulatory shock and impaired pulmonary gas exchange develop, advanced hemodynamic monitoring is required. As with other types of circulatory shock, fluid therapy, inotropic and vasopressor therapy, and optimization of ventilatory support require titration under hemodynamic guidance to maintain organ perfusion, pulmonary gas exchange, and systemic oxygen delivery.

Close attention to the airway is essential because laryngeal edema is an important cause of morbidity and death. Frequent assessment for hoarseness, stridor, and upper airway obstruction is required for patients whose airways are not protected with an endotracheal tube. The head and neck should be positioned to prevent airway obstruction by the tongue. If inspiratory stridor develops, endotracheal intubation should be attempted. Because intubation may be difficult in the presence of laryngeal edema, skilled personnel capable of performing difficult endotracheal intubations and emergency surgical airways should be available.

If intubated patients are unable to breathe spontaneously or have labored respirations, mechanical ventilation should be initiated. Positive end-expiratory pressure and other advanced ventilatory techniques are often necessary when hypoxemia, pulmonary edema, and decreased pulmonary compliance develop. In nonintubated patients, 6 to 8 L per minute of oxygen through a facemask is recommended.⁸⁰

The site of antigen introduction should be identified. If the patient is unconscious or unaware of the site of antigen introduction, a thorough search of skin surfaces should proceed. Retained stingers from *Hymenoptera* may be found and require complete and immediate removal. Delaying venomization from an extremity using a constricting band or local application of epinephrine or suctioning venom are controversial practices. However, immobilization is recommended. Thorough washing of the skin should follow exposure to antigen that has contacted the skin surface.

The mainstay of pharmacologic therapy for anaphylaxis is epinephrine. Epinephrine is of proven efficacy in reversing the bronchoconstriction and hypotension associated with anaphylaxis. The β -adrenergic effects of epinephrine inhibit mediator release by increasing intracellular levels of cAMP. In addition, β -adrenergic stimulation reverses bronchospasm, increases myocardial contractility, and increases heart rate. The α -adrenergic vasoconstrictive properties of epinephrine may increase diastolic pressure and enhance coronary flow.

All medical personnel should be aware that two dilutions of epinephrine are commonly available: 1 mg/mL or 1:1000 dilution and 0.1 mg/mL or 1:10,000 dilution. For the initial treatment of anaphylaxis, most authorities recommend that 0.3 to 0.5 mg of the 1:1000 solution (0.3 to 0.5 mL) be given intramuscularly. This dose may be repeated at 5- to 15-minute intervals if symptoms do not improve. In children, the recommended dose is 0.01 mg/kg not to exceed 0.5 mg.

Fluid therapy is an essential component of anaphylaxis treatment. Adults should receive 1 to 2 L of normal saline

Box 28.3 Pharmacologic Approach to the Acute Management of Anaphylaxis

Give epinephrine 0.3-0.5 mL of a 1:1000 solution intramuscularly with patient in a supine position. An additional dose may be repeated in 5- to 15-min intervals.

If patient remains in shock despite fluids and initial intramuscular epinephrine treatment, then intravenous epinephrine at the rate of 2-10 µg/min should be administered and titrated to effect.

Administer hydrocortisone 100-200 mg intravenously at 4- to 6-hour intervals (for severe cases). Taper rapidly as patient improves.

For Persistent Bronchospasm

Give aminophylline 5-6 mg/kg intravenously loading dose, then 0.4-0.9 mg/kg/min.

Give metaproterenol 0.2-0.3 mL (5% solution) in 2.5 mL normal saline solution administered by nebulization; repeat every 3-4 hours as needed.

Give ipratropium bromide aerosol (2 puffs) inhaled and repeated at 2-hour intervals.

Provide intravenous fluids according to degree of hemoconcentration or, in more severe cases, hemodynamic factors. Normal saline, Ringer's lactate, 5% human serum albumin. Hydroxyethyl starch should be avoided.

For Hypotension and Shock

For continued hypotension and other signs of circulatory shock start with an epinephrine drip.

- Epinephrine drip at 2-10 µg/min

One of the following vasopressors may be added for persistent hypertension:

- Norepinephrine drip 4-8 mg in 1 L normal saline at 4-8 µg/min
- Dopamine drip 200 mg in 0.5 L normal saline at 5-16 µg/kg/min

The following may be given if no contraindications:

- Diphenhydramine 25-50 mg orally or intravenously at 4-hour intervals

as soon as possible for severe anaphylaxis. Fluids reverse the intravascular volume deficits typical of anaphylaxis. Both crystalloidal and colloidal fluids are effective. Clinicians should be aware that two to three times as much crystalloid is required compared with colloid to achieve comparable intravascular volume repletion. However, colloid may trigger another anaphylaxis reaction by itself. Reversal of hemoconcentration is a reasonable resuscitative goal for patients who are stable and responding favorably to treatment. In unstable patients with wide fluctuations in vital signs and worsening pulmonary function, fluid therapy should be administered in the ICU with advanced hemodynamic monitoring capability.

If hypotension and other signs of circulatory shock persist after the initial administration of epinephrine and fluids, then intravenous epinephrine is recommended. Bolus doses are no longer recommended because of dosing errors and side effects.⁸¹ The initial dose for intravenous epinephrine infusion is 2 to 10 µg per minute, titrated to effect on blood pressure.⁸² Sometimes patients may need an additional vasopressor along with epinephrine.

ADDITIONAL THERAPEUTIC OPTIONS

Although the role of epinephrine in anaphylaxis is established, the role of antihistamines and corticosteroids continues to be debated.⁸⁰ Nonetheless, corticosteroids should be administered in severe cases of anaphylaxis because there is evidence that they prevent or attenuate late-phase reactions, increase tissue responsiveness to β-agonists, and inhibit the synthesis of histamine. Methylprednisolone or hydrocortisone may be given for 72 hours and can then be rapidly tapered off because almost all the biphasic reactions occur within 72 hours.^{83,84}

Inhalational drugs may be useful in patients with persistent bronchospasm. Inhalational β-agonists include metaproterenol and albuterol. Ipratropium bromide is an inhalational bronchodilator with anticholinergic properties and may have a favorable effect on mediator release by decreasing cGMP levels. This agent may be used in combination with inhalational β-agonists.

Laryngeal edema, if mild, may respond to nebulized racemic epinephrine. Localized vasoconstriction from the α-adrenergic properties of these drugs minimizes edema formation in the larynx and adjacent areas. Racemic epinephrine may be administered by nebulization (0.5 mL of a 2.25% solution diluted in 3.5 mL distilled water). Intravenous corticosteroid therapy also may be useful in this condition. Severe laryngeal edema associated with respiratory distress or stridor should always be treated with intubation of the trachea.

Several other agents have been used in cases of human anaphylaxis or in laboratory models of anaphylaxis with apparent success. Glucagon, a pancreatic hormone that increases intracellular cAMP levels by activating adenylate cyclase, was effective in a case report of a patient with anaphylaxis who was receiving beta-blocker therapy.^{85,86} Current research focuses on understanding mast cell and basophil biology, targeting tyrosine kinases, and developing antibodies to IgE.^{87,88}

Arrangements must be made for patients who have experienced anaphylaxis to receive follow-up care by a physician experienced in the management of acute allergic events. Skin testing may be required to identify the inciting agent. Instructions in self-treatment after antigen exposure are necessary. Autoinjectors of epinephrine 0.15 mg and 0.30 mg (1:1000) and oral antihistamines for patients to self-administer are available.

PROPHYLAXIS AND IMMUNOTHERAPY

If a patient must be treated with a drug that has previously produced severe allergic symptoms or anaphylaxis and no alternative exists, premedication should be implemented. Most authorities recommend premedication with H₁ and H₂ blockers and corticosteroids. Several studies have confirmed that premedication with these agents decreases anaphylactic reactions to radiocontrast media.⁸⁹⁻⁹¹ In very high risk patients, some authorities believe that epinephrine or isoproterenol should be included as premedication.⁹² Because fatal anaphylaxis has been described in patients who received premedication, it is preferable, if clinically possible, to avoid all antigens associated with anaphylaxis.

Methods to desensitize individuals immediately before administration of a drug have been described in detail, especially for penicillin,⁹³ aspirin,⁹⁴ and insulin.⁹⁵ These techniques, which involve exposure to antigen in 20- to 30-minute increments, may be unsuccessful, however, and occasional fatalities have been reported.⁹⁶⁻⁹⁸

Long-term desensitization may be useful in patients who have experienced anaphylaxis to antigens that are difficult to avoid, especially foods and venoms. This type of immunotherapy involves initial injection of a minute dose of antigen followed by gradual increases in dose at weekly or biweekly intervals according to the patient's tolerance.^{99,100} A non-IgE-blocking antibody forms and decreases the reactivity of mast cells and basophils to antigen.

Education and acute and long-term desensitization should be the responsibility of physicians experienced in the management of immediate hypersensitivity disorders. The critical care physician is responsible for ensuring the referral of patients who have experienced anaphylaxis to the care of appropriately trained specialists.

KEY POINTS

- Classic anaphylaxis is an IgE-mediated allergic reaction (type I) with acute systemic manifestations.
- Nonimmune and IgE-independent anaphylactic reactions are clinically identical to classic anaphylaxis and respond similarly to treatment.
- Mediators derived from mast cells and basophils are responsible for the major pathophysiologic effects of anaphylaxis.
- Eosinophils also release mediators that modulate the inflammatory response of anaphylaxis.
- Mediators from polymorphonuclear leukocytes and platelets are responsible for late-phase reactions after the initial anaphylactic event.
- Histamine, leukotrienes, and prostaglandins are important biochemical mediators of anaphylaxis. Release of these mediators is associated with increased vascular permeability and bronchial smooth muscle constriction.
- Pharmacologic agents that increase cAMP levels inhibit mediator release and may be beneficial in anaphylaxis.
- Agents that decrease cGMP levels (e.g., anticholinergic drugs) also inhibit mediator release.
- Fatal anaphylaxis is often associated with upper airway obstruction from laryngeal edema.
- The initial presentation of a patient with anaphylaxis depends on the portal of entry of the antigen and may include a local skin reaction and respiratory, upper airway, and gastrointestinal symptoms.
- Late-phase reactions may occur 6 to 12 hours after the initial anaphylactic event and are associated with a recurrence of symptoms.

KEY POINTS (Continued)

- Hemodynamic characteristics of anaphylaxis include tachycardia, hypotension, decreased cardiac filling pressures, and decreased systemic vascular resistance.
- The mainstays of anaphylaxis management are to (1) ensure airway patency, (2) remove or delay the absorption of toxins, (3) establish access for fluid therapy, and (4) initiate pharmacologic support with epinephrine.
- Corticosteroids should be given in severe cases to prevent late-phase reactions.
- Antihistamines (H₁ and H₂ blockers) are routinely given if there are no contraindications.
- Inhaled β -agonist agents, aminophylline, and inhaled anticholinergic agents may be given for continued bronchospasm.
- All patients who have experienced anaphylaxis should be referred to an appropriately qualified specialist for follow-up. These patients may require allergy testing, desensitization, and premedication strategies.

ACKNOWLEDGMENT

The authors would like to thank Ravi Chandra Gutta, MD, for his assistance in reviewing and critiquing this manuscript.

DEFINITION, EPIDEMIOLOGY, AND STAGING OF HEART FAILURE

Heart failure can be defined as an inability of the heart to provide cardiac output adequate to meet the metabolic demands of the body at a normal filling pressure. The term *heart failure* commonly refers to a syndrome of signs and symptoms caused by excessive salt and fluid retention, increased left and right ventricular filling pressures, and decreased cardiac output. Heart failure is a progressive illness with a high mortality rate. Death can occur either at the end of progressive worsening of the heart failure syndrome or suddenly and unexpectedly in patients who appear clinically stable. Appropriate therapies for heart failure, involving medications, revascularization, and devices, have the potential to reverse the processes that cause heart failure and thus improve cardiac performance, which can result in stabilization of the patient's symptoms, enhance functional status, and improve chances for survival.

Heart failure is a very common illness; 5.8 million Americans are affected.^{1,2} It is estimated that 1% of the

population of Americans over the age of 65 are affected by heart failure, and 20% of hospital admissions in patients over age 65 are due to heart failure.³ Men and black Americans are affected more frequently. In 2008 670,000 new cases of heart failure were diagnosed in the United States, where there are nearly 1 million hospital discharges, 658,000 visits to the emergency department, over 3.4 million ambulatory outpatient visits, and 6.5 million hospital days annually for patients with a primary diagnosis of heart failure.^{1,2} Over 56,000 people in the United States died in 2007 with heart failure as the primary cause. The treatment of heart failure incurs a very large economic burden on the U.S. health care system. Estimated direct and indirect cost of heart failure in 2010 was \$29 billion. The majority of this cost was related to the treatment of patients hospitalized with heart failure.

Epidemiologic data showed significant increases in both the incidence and prevalence of heart failure in the U.S. population in the 1990s,³ likely influenced by the aging of the population, a high prevalence of hypertension, and improved treatment and survival of patients with ischemic

heart disease.⁴ However, there is evidence that hospitalizations for heart failure have declined during the past decade. In the United States, the rate of hospitalization for heart failure declined from 2845 per 100,000 patient-years in 1998 to 2007 per 100,000 person-years in 2008, a decline of 29%.⁵

Patients hospitalized with acute heart failure are usually elderly, with a mean age in the early 70s. In the United States, roughly 80% of patients will have a previous history of heart failure,⁶ and in European studies one third of patients had a new diagnosis of heart failure.⁷ From 40% to 55% of patients will have normal or relatively normal left ventricular systolic function. This occurs more commonly in women than in men. Coronary heart disease is present in 50% to 60% of patients and hypertension in 72% of patients. Comorbid conditions are common, including

renal disease in 30% of patients, diabetes mellitus in 43%, and chronic obstructive pulmonary disease (COPD) in roughly 30%.^{6,8}

In the American College of Cardiology/American Heart Association Guidelines for the diagnosis and management of chronic heart failure, four stages in the development of heart failure are recognized (Fig. 29.1). This staging system emphasizes the progressive nature of left ventricular dysfunction and heart failure, and describes evidence-based guidelines for therapy for each stage.⁴ It is important to realize that heart failure may be preventable. Several common medical conditions place patients at high risk for developing left ventricular dysfunction and the heart failure syndrome. Attention to and appropriate management of these conditions may prevent the development of heart failure. In addition, in patients who have left ventricular

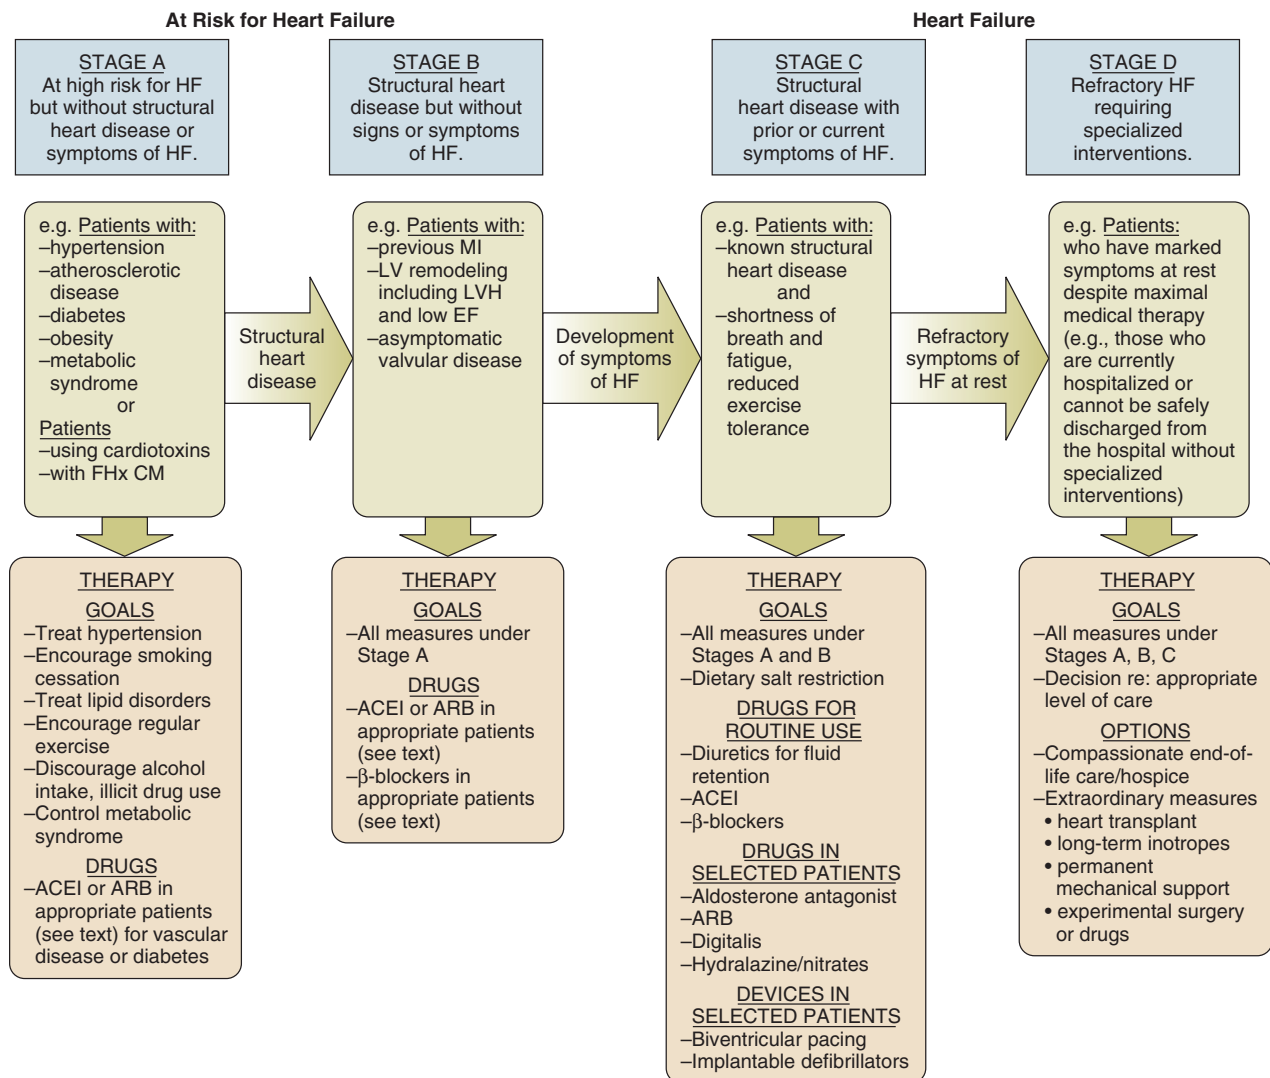

Figure 29.1 Stages in the development of heart failure and recommended therapy by stage. (Redrawn from Hunt S, Abraham WT, Chin M, et al: ACC/AHA 2005 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult—Summary Article. A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society for Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation* 2005;112:1825-1852.)

dysfunction but who have not yet developed heart failure, appropriate therapy can improve prognosis and prevent the development of severe heart failure.

Stage A represents patients at high risk for heart failure but without structural heart disease or symptoms of heart failure. These patients include those with hypertension, atherosclerotic heart disease, diabetes, obesity, or the metabolic syndrome; those exposed to cardiotoxic medications; and those with a family history of cardiomyopathy. About 75% of patients who develop heart failure have antecedent hypertension.² Stage B patients have structural heart disease but without signs or symptoms of heart failure. This group includes patients who have suffered a myocardial infarction, those with abnormal left ventricular ejection fraction but no symptoms of heart failure, and those patients with asymptomatic valvular heart disease. Stage C patients have structural heart disease with prior or current symptoms of heart failure, such as shortness of breath, fatigue, and reduced exercise tolerance. Lastly, stage D patients have refractory symptoms of heart failure at rest despite maximal medical therapy. They require specialized or extraordinary interventions such as cardiac transplantation, mechanical circulatory support, or end-of-life care.

PATHOPHYSIOLOGY

Heart failure can be due primarily to left ventricular systolic dysfunction or diastolic dysfunction, although both abnormalities are often present together. Right ventricular dysfunction may accompany left ventricular dysfunction or may be the primary problem. Systolic heart failure results from inability of the heart to expel blood normally owing to depressed left ventricular contraction. The left ventricle is often dilated. There is loss of myocytes and fibrosis, resulting in reduced left ventricular ejection fraction. Diastolic heart failure is caused by a reduction in left ventricular compliance, which leads to impaired diastolic filling, higher left ventricular diastolic pressure, and elevated pulmonary capillary wedge pressure (PCWP). Diastolic heart failure is also called heart failure with preserved ejection fraction (HFpEF) or heart failure with normal ejection fraction (HFnEF) (Fig. 29.2A and B).

Numerous conditions may cause damage to left ventricular myocardium and result in systolic heart failure. The most common of these conditions is atherosclerotic coronary artery disease with myocardial infarction and chronic

Figure 29.2 A, Left ventricle (LV) remodeling after acute myocardial infarction, resulting in a dilated LV with global systolic dysfunction. B, Ventricular remodeling in diastolic and systolic heart failure. Note differences in LV morphology in diastolic versus systolic heart failure. (Redrawn from Jessup M, Brozena S: Heart failure. *N Engl J Med* 2003;348:2007-2018.)

myocardial ischemia. Other common causes include hypertension; familial and idiopathic cardiomyopathy; viral myocarditis; valvular heart disease, such as aortic stenosis, aortic insufficiency, and mitral regurgitation; peripartum cardiomyopathy; transient apical ballooning syndrome (takotsubo cardiomyopathy); and cardiomyopathy due to cardiotoxic cancer chemotherapy. Less common causes are alcoholic cardiomyopathy, diabetic cardiomyopathy, and a cardiomyopathy seen in some patients with hyperthyroidism or severe obesity.⁹⁻¹¹

After myocardial damage and loss of myocytes occur, a process known as ventricular *remodeling* is initiated. This remodeling results in dilation of the ventricular chamber, a change in ventricular geometry from ellipsoid-like to a more spherical shape, worsening of left ventricular contractile force, and reduction in ventricular ejection fraction.^{3,12} In addition, the change in left ventricular geometry often leads to an increase in the size of the mitral annulus and altered physical relationships of the mitral valve structures. This results in increasing mitral regurgitation and worsening of the heart failure syndrome (see Fig. 29.2).

Remodeling is mediated by a series of maladaptive systemic responses, commonly termed *neurohormonal activation*. Two major systems involved in neurohormonal activation are the renin-angiotensin-aldosterone system and the sympathetic nervous system. Activation of the renin-angiotensin-aldosterone system leads to elevated levels of renin, angiotensin II, and aldosterone, which has deleterious consequences on cardiac function and hemodynamics.^{3,12} These effects include salt and fluid retention, endothelial dysfunction, vasoconstriction, myocyte hypertrophy, myocardial fibrosis, and myocyte apoptosis (programmed cell death). Sympathetic nervous system activation is in part mediated via decreased cardiac output, which results in tachycardia, increased myocardial oxygen consumption, and peripheral vasoconstriction.¹³ Renal effects of sympathetic nervous system activation lead to further activation of the renin-angiotensin-aldosterone system. Increased circulating norepinephrine levels also contribute to myocyte injury and death. Arrhythmias become common. A detrimental positive feedback loop is established, causing progressive deterioration in left ventricular structure and performance over time with progressive worsening of chronic heart failure.

Conditions commonly associated with diastolic heart failure include hypertension, left ventricular hypertrophy, and acute coronary ischemia. Diastolic heart failure is common in elderly populations, especially in women, likely due to progressive diastolic compliance abnormalities seen with aging. Uncommon conditions leading to diastolic heart failure include infiltrative and restrictive cardiomyopathies, such as amyloid cardiomyopathy, and chronic constrictive pericarditis.

DIAGNOSIS

Heart failure is a clinical diagnosis, determined after evaluation of a patient's symptoms and physical examination and supported by results of ancillary testing, such as chest x-ray and echocardiography. Typical symptoms of heart failure include shortness of breath at rest or with exertion, cough,

swelling, orthopnea, and paroxysmal nocturnal dyspnea, which are due to pulmonary or systemic venous congestion. Fatigue, anorexia, and change in mental status are symptoms that may be caused by low cardiac output. Physical examination often reveals pulmonary rales; elevated jugular venous pressure; signs of cardiomegaly; cardiac murmurs, especially mitral regurgitation and third heart sound (S_3) gallop; hepatic enlargement; and ascites and edema. An S_3 gallop and elevated jugular venous pressure are the most specific signs of heart failure; absence of rales is not infrequent in patients with acute heart failure, and chest radiograph may not show obvious congestion.¹⁴ Manifestations of more severe heart failure include marked dyspnea at rest, possibly resulting in respiratory failure, cyanosis, cool extremities, reduced urine output and altered mental state. A careful evaluation for the presence of pulsus paradoxus is important if cardiac tamponade is suspected. However, these signs and symptoms are not specific for heart failure, and coexisting conditions such as obesity, chronic lung disease, and deconditioning can add uncertainty to the clinical diagnosis. Heart failure is often both underdiagnosed and overdiagnosed in outpatient and emergency department settings.

Studies have shown that serum assays of B-natriuretic peptide (BNP) and N-terminal pro-BNP are very helpful in improving the accuracy of diagnosing heart failure. BNP is a 32-amino acid peptide produced by cardiac myocytes in response to pressure-induced wall stretch and tension.¹⁵ Physiologic actions of BNP include arterial and venous dilation and natriuresis. A study of 1530 patients presenting to the emergency department with dyspnea showed that knowledge of BNP serum levels resulted in improved accuracy of the diagnosis of heart failure when compared to clinical judgment alone, from an initial range of 65% to 74%, up to 81% accuracy.¹⁶ BNP levels above 100 pg/mL had a sensitivity of 90% and a specificity of 76% for the diagnosis of heart failure and were very useful for discriminating patients with dyspnea due to uncomplicated lung disease who had BNP values below 100 pg/mL.¹⁷ Patients with BNP values below 100 pg/mL were very unlikely to have heart failure as the cause of dyspnea. Levels between 100 and 400 pg/mL can be seen in dyspneic patients with cor pulmonale, pulmonary hypertension not due to left ventricular failure, and acute pulmonary embolism. Heart failure is the likely diagnosis when levels are above 400 pg/mL. It should be emphasized that BNP levels should always be used in conjunction with all other clinical data to arrive at the correct diagnosis.

Evaluating BNP levels in heart failure patients in the emergency department was shown to decrease the need for hospitalization and decrease the need for intensive care unit (ICU) admissions, without affecting 30-day mortality rates.¹⁸ Total hospital stay was shortened by 3 days, cost of treatment was significantly reduced, and time to initiation of definitive therapy in the emergency department was shortened by 30 minutes.

BNP levels correlate with disease severity, as values are higher in patients with more severe heart failure and with worse left ventricular systolic function. Higher levels also have been correlated with a poorer prognosis, and can predict an increased rate of functional deterioration and a higher mortality rate.¹⁹ In a study of 114 patients admitted

to the hospital with class IV heart failure, of all variables evaluated, predischARGE BNP level was most strongly associated with death or readmission within 6 months, with BNP levels greater than 350 pg/mL having impressive sensitivity and specificity.²⁰ BNP levels may also be elevated in patients with diastolic heart failure, those with renal failure, and stable patients with chronic left ventricular systolic dysfunction with compensated heart failure. BNP levels may initially be low in patients with “flash” pulmonary edema, as they may present to the hospital more quickly than the time required for significant rises in serum BNP to occur.

Serum levels of N-terminal (NT) pro-BNP can also be used for the diagnosis of heart failure. A precursor hormone, pro-BNP, is cleaved to form BNP and NTpro-BNP, which is physiologically inactive. NTpro-BNP has a longer half-life than BNP. It is cleared from the serum by the kidneys, so levels are higher in patients with coexisting renal disease. Levels of NTpro-BNP rise significantly in older populations. A cut off level of NTpro-BNP below 300 pg/mL yielded a negative predictive value of 98% for exclusion of the diagnosis of heart failure.^{21,22} The diagnosis of heart failure is very likely at levels over 450 pg/mL for patients under age 50, above 900 pg/mL in patients between 50 and 75 years old, and above 1800 pg/mL in patients over the age of 75.

PROGNOSIS IN ACUTE HEART FAILURE

Hospitalization for acute heart failure is associated with a poor prognosis. In-hospital mortality rate is high, reported at 4% to 8%. There is a 9% mortality rate at 60 to 90 days, and a 1-year mortality rate of 29%.^{1,6,7,23-25} The 90-day rehospitalization rate is around 30%, although only half of these rehospitalizations are caused by heart failure. In a European heart failure database, in-hospital mortality rate was 6.9%, 12-week readmission rate was 24%, and total mortality rate at 12 weeks was 13.5%.⁸ Randomized trials of pharmacologic therapy reported an annual mortality rate of 10% in patients with class II-III symptoms and 20% to 50% in class IV patients. In the most severe chronic heart failure group, patients awaiting cardiac transplantation, 1-year mortality rate was 75% with 2-year mortality rate of 92%.²⁶ More recent data indicate a decline in the risk-adjusted inpatient mortality rate, from 5.5% in 2000 to 2.8% in 2007. Similar reductions were seen in both sexes and across all age groups.²⁷ The prognosis for patients with cardiogenic shock due to acute myocardial infarction continues to be poor. Mortality rate remains 40% to 50% even with aggressive supportive therapy and emergency revascularization strategies.²⁸

Several clinical factors have been shown to identify patients with a poorer prognosis and include lower left ventricular ejection fraction, low blood pressure on admission, and higher PCWP. In the United States ADHERE database registry of 62,275 admissions for heart failure, blood urea nitrogen (BUN) greater than 43 mg/dL, admission systolic blood pressure under 115 mm Hg, and creatinine level greater than 2.75 mg/dL were the three factors that indicated a poor prognosis for patients admitted with acute heart failure. The presence of an elevated BUN was associated with a fourfold increase in hospital mortality rates to

Box 29.1 Factors Indicating a Poor Prognosis in Acute Heart Failure

- Hypotension (systolic blood pressure <115 mm Hg on admission)
- Presence of coronary artery disease
- Elevated blood urea nitrogen and serum creatinine
- Hyponatremia
- Low left ventricular ejection fraction
- Poor functional capacity
- Elevated serum biomarkers—B-natriuretic peptide, troponin
- Anemia
- Diabetes mellitus

Adapted from Nieminen MS, Bohm M, Cowie MR, et al: Executive summary of the guidelines on the diagnosis and treatment of acute heart failure. The Task Force on Acute Heart Failure of the European Society of Cardiology. *Eur Heart J* 2005;26:384-416.

8.35%. The presence of all three factors yielded an in-hospital mortality rate of 19.8%²⁴ (Box 29.1).

Other factors associated with increased mortality rates include hyponatremia, higher serum BNP level, and elevation of serum troponin.^{6,29,30} In ADHERE, higher levels of serum BNP on admission were associated with a higher in-hospital mortality rate, ranging from 1.9% in the lowest quartile to 6.0% in the highest quartile (BNP over 1730 pg/mL). The ability of BNP to predict prognosis was present even after multivariate adjustment for coexisting conditions, and was also true for patients with normal and abnormal left ventricular ejection fraction.³¹ Serum troponin is elevated in 6% to 10.4% of patients admitted with acute heart failure (with serum creatinine <2.0 mg/dL). Troponin elevation was associated with a lower blood pressure, lower ejection fraction, and longer hospital length of stay. Hypothetical mechanisms of troponin release in chronic heart failure include ischemia, cytokine activation, oxidative stress, and apoptosis. Hospital mortality rate was 8.0% in troponin-positive patients and 2.7% if troponin-negative. The ability of troponin elevation to predict mortality rate also was independent of other variables and was true even in patients with nonischemic causes of heart failure.³²

The coexistence of kidney disease significantly worsens the prognosis of patients with heart failure. Kidney disease aggravates the tendency to volume overload and heart failure decompensation, and heart failure often worsens renal function. This complex interaction of severe heart failure and worsening kidney function is called the *cardiorenal syndrome*. In addition, high-dose diuretic therapy may also temporarily worsen renal function. There is increasing evidence that elevated systemic venous pressure causing renal venous congestion plays an important role in the pathogenesis.³³ In a retrospective study of patients with acute heart failure who had right-sided heart catheterization, elevated central venous pressure was associated with reduced glomerular filtration rate (GFR) and higher all-cause mortality rate. These findings were independent of the measured cardiac output.³⁴ Up to 50% of patients hospitalized with heart failure demonstrate a GFR less than

60 mL/minute/m², and renal function may worsen in up to 30% of patients admitted with heart failure.³⁵ Patients at particular risk for developing worsening renal function are those with lower left ventricular ejection fractions, lower blood pressure, diabetes mellitus, a history of hypertension, and older age. These patients have longer hospital stays and higher readmission and mortality rates. A meta-analysis of 16 large studies of heart failure patients revealed that 29% of heart failure patients had moderate to severe impairment of renal function. These patients had more than 100% increased relative mortality risk. Any degree of renal impairment had an approximately 50% increased relative mortality risk.³⁶ The best treatment strategy for these patients is not clear, as patients with significant renal impairment have generally been excluded from large randomized pharmacologic heart failure trials.

ACUTE HEART FAILURE SYNDROMES

INITIAL EVALUATION AND THERAPY

Acute heart failure is defined as the rapid onset of severe symptoms of heart failure, usually within hours to several days. Acute heart failure can occur with predominant systolic or diastolic dysfunction. Acute heart failure is often life-threatening and requires urgent diagnostic and therapeutic interventions, often simultaneously.²³ Acute myocardial ischemia is a common cause and should

always be considered in the differential diagnosis of this syndrome.

Several distinct clinical syndromes of acute heart failure can be identified²³ (Table 29.1).

1. Acute worsening or decompensation of chronic heart failure symptoms, either in the setting of known chronic cardiovascular illness or de novo. These patients do not have shock or pulmonary edema. This is the most common presentation of acute heart failure requiring admission to hospital, occurring in approximately 70% of patients with acute heart failure.
2. Acute pulmonary edema with normal blood pressure, often caused by acute myocardial infarction or acute coronary ischemia.
3. Acute pulmonary edema associated with elevated blood pressure, often in the setting of chronic severe hypertension and chronic kidney disease. Pulmonary edema accounts for roughly 25% of acute heart failure admissions.
4. Cardiogenic shock with heart failure, usually due to acute myocardial infarction. This syndrome is the most severe presentation of acute heart failure and is associated with high in-hospital mortality rates. This accounts for about 5% of acute heart failure cases.
5. “High cardiac output heart failure” often induced by sepsis, hyperthyroidism, or cardiac arrhythmia. This type is the least common presentation, occurring in a small percentage of patients.

Table 29.1 Acute Heart Failure Syndromes

Syndrome	Onset	Signs and Symptoms	Hemodynamics
Acute decompensated heart failure	Days weeks	Weakness Dyspnea Rales Third heart sound (S ₃) gallop Edema	↑ PCWP ↓ CI Normal or ↑ RAP ↑ SVR
Acute pulmonary edema, normal BP	Abrupt-days	Severe dyspnea Diffuse rales Cyanosis S ₃ gallop	↑↑ PCWP Normal or ↓ CI Normal RA Normal or ↑ SVR
Acute pulmonary edema with hypertension	Acute	Severe dyspnea Diffuse rales	↑↑ PCWP Normal CI Normal RAP ↑↑ SVR
Cardiogenic shock	Acute	Hypotension Cyanosis Lethargy Cool, clammy	↑↑ PCWP ↑ RAP ↓↓ CI ↑ SVR
High-output heart failure	Days-weeks	Dyspnea Rales	↑ PCWP ↑ CI ↓ SVR
RV failure	Days-weeks	Hypotension Edema Ascites	Normal or ↑ PCWP ↑↑ RAP ↓↓ CI

BP, blood pressure; CI, cardiac index; PCWP, pulmonary capillary wedge pressure; RAP, right atrial pressure; RV, right ventricular; SVR, systemic vascular resistance; ↑, increased; ↑↑, markedly increased; ↓, reduced; ↓↓, markedly reduced.

Adapted from Nieminen MS, Bohm M, Cowie MR, et al: Executive summary of the guidelines on the diagnosis and treatment of acute heart failure. The Task Force on Acute Heart Failure of the European Society of Cardiology. *Eur Heart J* 2005;26:384-416; and Gheorghiade M, Zannad F, Sopko G: Acute heart failure syndromes. *Circulation* 2005;112:3958-3968.

6. Acute right ventricular failure, occurring with acute right ventricular myocardial infarction, massive pulmonary embolism, or cardiac tamponade.

Symptoms of acute heart failure are similar to those of chronic heart failure but are more severe. Symptoms of tissue hypoperfusion, such as fatigue, weakness, confusion, nausea, and anorexia, may be subtle but are important to recognize as they may herald impending cardiogenic shock. Chest pain may indicate acute coronary ischemia.

Physical examination often shows pulmonary rales and wheezes, an S_3 gallop, and elevation of jugular venous pressure. Peripheral pulses are weak and thready with diminished cardiac output states. A low cardiac output is reliably predicted by a low “proportional pulse pressure,” which is calculated by the pulse pressure (systolic blood pressure minus diastolic blood pressure) divided by systolic blood pressure. A ratio below 0.25 predicts a cardiac index below 2.2 L/minute/ m^2 .^{37,38} The skin may be cool and clammy and there may be evidence of cyanosis. Peripheral edema and ascites may indicate concomitant right ventricular failure of longer duration. Chest radiography is done urgently. An electrocardiogram (ECG) is needed to assess for signs of ischemia and infarction, and to evaluate for arrhythmia. Cardiac rhythm needs to be monitored continuously. Laboratory examination includes evaluation of hemoglobin and hematocrit, electrolytes, renal and liver function, thyroid profile, and cardiac biomarkers (troponin I or troponin T) to look for evidence of myocardial necrosis. BNP level assists in the diagnosis of heart failure in patients presenting with dyspnea, and can be followed serially to assess effectiveness of therapy. Pulse oximetry helps to assess oxygenation and pulmonary function. An arterial line is helpful in managing patients with hypotension or cardiogenic shock. Urgent two-dimensional echocardiography is essential to evaluate left ventricular size and function, right ventricular function, valve function, and the presence of pericardial effusion. Doppler echocardiographic assessment of valve stenosis and regurgitation and of hemodynamics is invaluable.

When patients are admitted to hospital with acute decompensation of chronic systolic heart failure, the specific reason for a patient's deterioration must be searched for and corrected when possible (Box 29.2). Environmental factors such as excessive salt and fluid intake or alcohol consumption are common. Patient adherence to outpatient therapies must be assessed, as heart failure regimens often involve numerous medications. Emotional and physical stressors should be corrected when feasible.

Concomitant administration of medications for noncardiac conditions can have detrimental effects. A partial listing includes corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs). These drugs can cause fluid retention and can aggravate hypertension. NSAIDs also interfere with the beneficial renal effects of angiotensin-converting enzyme (ACE) inhibitors and can interfere with the action of loop diuretics.³⁹ The use of NSAIDs has been reported to increase the risk of hospitalization for heart failure by tenfold in patients with a history of heart failure.⁸ Metformin and thiazolidinediones can contribute to water retention and aggravate the symptoms and signs of heart failure. Cancer chemotherapies can cause myocardial damage. Cardiac

Box 29.2 Causes of Acutely Decompensated Heart Failure

Environmental Causes

- Excess salt and fluid intake
- Excess alcohol consumption
- Medication noncompliance or misunderstanding
- Emotional or physical stress

Adverse Medication Effects

- Calcium channel blockers
- Antiarrhythmic agents (types 1A, 1C)
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Corticosteroids
- Metformin, thiazolidinediones
- Cancer chemotherapy

Cardiovascular Conditions

- Acute ischemia/infarction
- Pulmonary embolism
- Uncontrolled hypertension
- Arrhythmia
- Worsening valvular regurgitation
- Endocarditis

Extracardiac Illness

- Sepsis, infection, hypoxia
- Renal failure, urinary obstruction
- Thyroid disease
- Anemia, blood loss
- Obstructive sleep apnea
- Bilateral renal artery stenosis
- Worsening of chronic lung disease

toxicity due to anthracycline chemotherapy is well described. Tyrosine-kinase inhibitors, a newer class of cancer chemotherapy, are also being recognized as agents that can aggravate heart failure and cardiomyopathy.⁴⁰ Cardiac medications such as calcium channel blockers and antiarrhythmic drugs can also have direct negative effects on left ventricular contractility. Calcium channel blockers are generally contraindicated in patients admitted with acute decompensated heart failure.²³ Type 1A and 1C antiarrhythmic drugs are also contraindicated in patients with abnormal left ventricular systolic function.

Acute and chronic extracardiac conditions may also cause heart failure decompensation. Pulmonary embolus, infectious illnesses, and sepsis occur commonly. Anemia, blood loss, and thyroid disease need to be assessed and corrected. Renal failure often has etiologic factors similar to those of heart failure (e.g., hypertension, vascular disease), and worsening renal function will often aggravate heart failure. Obstructive sleep apnea can lead to exacerbation of heart failure symptoms and can be effectively treated. Influenza and pneumococcal vaccines should be administered to patients to prevent the cardiac decompensation associated with respiratory infections.

Lastly, coexistent cardiovascular illness can aggravate heart failure. Acute or chronic coronary ischemia should always be suspected, evaluated, and corrected with revascularization strategies when appropriate. Uncontrolled

hypertension and cardiac arrhythmias (most commonly atrial fibrillation and ventricular arrhythmias) frequently accompany left ventricular dysfunction. Worsening valve regurgitation, endocarditis, and bilateral renal artery stenosis are other examples of conditions that can lead to heart failure exacerbations that are treatable.

There are few controlled-trial data to arrive at evidence-based guidelines for the treatment of acute heart failure. Many recommendations are based on small studies, experience, observation, and a general consensus of opinion.⁴¹ The goals of initial therapy are to improve symptoms, optimize blood pressure, lower PCWP, and improve cardiac output. Treatments to reverse or prevent myocardial injury are instituted, and a search for reversible causes of heart failure needs to occur. Optimization of other comorbid conditions is important, including hyperglycemia, renal disease, and pulmonary function.

Initial therapy includes supplemental oxygen and assessment of the need for ventilatory assistance with noninvasive positive airway pressure ventilation or endotracheal intubation. Noninvasive ventilation improves oxygenation and pulmonary compliance and decreases work of breathing. Endotracheal intubation may be required for patients with severe hypercapnia, acidosis, and respiratory muscle fatigue. The use of continuous oxygen administration alone was prospectively compared with the use of continuous positive airway pressure ventilation (CPAP) and noninvasive intermittent positive pressure ventilation (NIPPV) in 1069 patients who presented with acute cardiogenic pulmonary edema. No difference among these therapies was noted in the primary end point of death at 7 days, or in the secondary end point of death plus endotracheal intubation at 7 days. Noninvasive ventilation did result in more rapid improvement in dyspnea, tachycardia, hypercapnia, and acidosis. There was no difference in safety or efficacy between CPAP and NIPPV.⁴²

Initial medical therapy includes intravenous morphine, which acts as a vasodilator and often reduces heart rate. Intravenous loop diuretics, such as furosemide, offer rapid and effective symptom relief and are almost always prescribed. Intravenous vasodilators are very useful, especially in patients with severe hypertension; intravenous nitroglycerin and intravenous nitroprusside are used most commonly. Beta blockers should be given early to patients with heart failure and ischemic chest pain, hypertension, or tachyarrhythmias. They should be used with caution in patients with severe heart failure and should be withheld initially in the presence of hypotension, shock, bradycardia, or heart block. Calcium channel blocking agents are generally contraindicated in the acute setting.

Treatment of arrhythmias is essential. Rapid atrial fibrillation is a common problem in these patients. In the Euroheart Failure Study, 9% of patients hospitalized with acute heart failure had atrial fibrillation during the hospitalization, and 42% had a history of paroxysmal atrial fibrillation.⁴³ Other studies report atrial fibrillation in 25% to 30% of hospitalized heart failure patients.³⁶ Control of the ventricular response to atrial fibrillation is vitally important, especially in patients with diastolic heart failure. This control can be achieved rapidly with the use of intravenous beta blockers such as metoprolol or esmolol, parenteral digoxin, or intravenous amiodarone. Intravenous diltiazem can be

used in patients whose left ventricular systolic function is known to be normal or near normal.

INDICATIONS FOR INVASIVE HEMODYNAMIC MONITORING

Placement of a pulmonary artery (PA) catheter enables the clinician to accurately measure PCWP, cardiac output, and mixed venous oxygen saturation. It can also help assess the effectiveness of therapy. Whether to *routinely* use PA catheters to assess and manage patients with acute heart failure has been long debated. The ESCAPE trial evaluated the routine use of PA catheterization in patients hospitalized with acute exacerbation of chronic heart failure and left ventricular systolic dysfunction.⁴⁴ There was no difference in the primary end point of days alive out of the hospital during 6 months after discharge in groups managed with or without a PA catheter. There were no significant adverse effects with PA catheter use in this study. There were no subgroups identified in which use of the PA catheter was beneficial. However, there was a trend noted in improving the initial diuresis, with less deterioration of renal function, in the PA catheter group. The authors concluded that there was no indication for the *routine* use of PA catheters in the setting of acute heart failure.

However, a PA catheter is often essential for the management of patients with acute severe heart failure. Findings on physical examination are often insensitive indicators of hemodynamic status. Indications for PA catheter use include cardiogenic shock, differentiating pulmonary from cardiac causes of dyspnea, hemodynamic assessment if one is unsure of the diagnosis or severity of heart failure by clinical assessment, worsening renal function, guiding parenteral vasodilator therapy, and in patients who are not improving with initially prescribed therapy.³⁷ PA catheter placement is also necessary as part of the evaluation for cardiac transplantation or the implantation of a ventricular assist device (VAD) (Box 29.3).

Consecutive patients with severe heart failure were evaluated and classified according to hemodynamic measurements of PCWP and cardiac index. Patients were described as “dry” with average PCWP less than 17 mm Hg, or “wet” with PCWP reading of 29 mm Hg on average. The patients were also described as “warm” versus “cold,” based on a cardiac index of greater than 2.1 L/minute/m² versus an

Box 29.3 Indications for Invasive Hemodynamic Monitoring with a Pulmonary Artery Catheter in Acute Heart Failure

1. Cardiogenic shock
2. Cardiac or pulmonary cause of dyspnea not certain
3. Uncertainty regarding severity of heart failure
4. Worsening renal function during heart failure therapy
5. Guiding parenteral vasodilator therapy
6. Deteriorating heart failure status despite appropriate therapy
7. Evaluation prior to cardiac transplantation

index of less than 1.6 L/minute/m². The severity of symptoms and findings on physical examination did not predict the hemodynamic status as defined by invasive monitoring. In addition, the hemodynamic picture did not predict the response to therapy and survival was similar in all four groups, except that patients with higher cardiac output and lower PCWP had slightly better outcomes than patients with low cardiac output and high PCWP.⁴⁵

Tailoring pharmacologic therapy to hemodynamic measurements is often helpful and necessary to determine precise measurements of cardiac output and left ventricular filling pressure, in order to guide intensive intravenous drug therapy. Aggressive therapy tailored to the response in hemodynamic measurements has been advocated as an effective method to obtain more rapid and sustained improvement in patients with the most severe heart failure.⁴⁶ When PCWP is reduced to less than 16 mm Hg, and right atrial pressure is reduced to less than 8 mm Hg, most patients will improve acutely and for the remainder of their hospitalization. Additional hemodynamic goals include reducing systemic vascular resistance to less than 1200 dynes × sec/cm⁵, raising cardiac index to greater than 2.6 L/minute/m², and maintaining systolic blood pressure over 80 mm Hg. PCWP can be lowered to a normal value of 10 to 12 mm Hg in many patients with significant left ventricular dysfunction without untoward effects.^{46,47} In a group of patients referred for cardiac transplantation, a combination of aggressive parenteral therapy, targeted to optimal hemodynamics, followed by conversion to appropriate oral therapy, resulted in clinical improvement so that 30% of these patients were able to be removed from transplant lists.⁴⁶

PHARMACOLOGIC MANAGEMENT OF ACUTE HEART FAILURE

Goals of treatment of heart failure can be defined as short-term, to relieve dyspnea and reverse acute hemodynamic decompensation, and long-term, to prevent rehospitalization, improve functional status, and prolong survival. Additional goals include preserving renal function, preventing arrhythmias, and preventing myocardial necrosis in patients with ischemic and nonischemic disease. Pharmacologic therapies to prevent or attenuate chronic remodeling should be instituted or strengthened prior to discharge from the hospital, as these have been shown to improve long-term survival (Box 29.4).

Pharmacologic treatment of heart failure is aimed at achieving these goals by improving fluid balance and reversing the neurohormonal activation responsible for the progressive decline in left ventricular function. Therapy usually involves combinations of multiple medications. Several drugs have been shown to improve symptoms and functional capacity, decrease the need for repeated hospitalizations, and improve mortality rates.

Careful serial assessment of patients is mandatory to guide pharmacologic therapy. Signs of heart failure on physical examination are important to follow, including daily weights, pulmonary rales, the presence of an S₃ gallop, jugular venous pressure, urine output, and pulse oximetry.

Box 29.4 Goals of Therapy During Hospitalization for Acute Heart Failure

Clinical Changes

- Decreased dyspnea and orthopnea, improved exercise tolerance
- Improved pulmonary function and oxygenation
- Diuresis
- Decreased body fluid weight and edema
- Systolic blood pressure maintained >80 mm Hg

Laboratory Data

- Normalized serum electrolyte levels
- Optimized renal function
- Decreased serum B-natriuretic peptide levels

Hemodynamics

- Pulmonary capillary wedge pressure <16 to 18 mm Hg
- Right atrial pressure <8 mm Hg
- Normalized cardiac index

Improve Prognosis

- Treatment of ischemia
- Evidence-based pharmacologic therapy initiated
- Evaluation for use of device therapy (cardiac resynchronization therapy, implantable cardioverter defibrillator)

Table 29.2 Loop Diuretics Used for the Treatment of Acute, Severe Heart Failure

Agent	Oral Dose	Initial IV Dose (mg)	Maximum IV Bolus Dose (mg)
Bumetanide	0.5-1.0	1.0	4-8
Furosemide	20-40	40	160-200
Torsemide	10-20	10	100-200

IV, intravenous.

INTRAVENOUS DIURETICS

Although no randomized clinical trials exist, the use of loop diuretics is supported by a long history of clinical success. These agents increase renal excretion of salt and water. The onset of action of intravenous bolus furosemide is 30 minutes, and the drug peaks at 1 to 2 hours. The half-life of the medication is 6 hours, so twice daily dosing is usually required.³⁹ Other loop diuretics often used are bumetanide and torsemide (Tables 29.2 and 29.3). Several small clinical trials suggested that a constant infusion of a loop diuretic resulted in superior diuresis when compared to intermittent bolus dosing,^{48,49} although other studies did not confirm this.⁵⁰ A large, randomized controlled study was performed

Table 29.3 Treatment of Refractory, Diuretic-Resistant Heart Failure

To Loop Diuretic, add:	Dose
Hydrochlorothiazide	25-50 mg once or twice daily
or metolazone	2.5-5.0 mg once or twice daily
or spironolactone	12.5-50 mg once daily

in patients hospitalized with acute decompensated heart failure who were taking a high dose of furosemide prior to admission. Patients were randomized within 24 hours of admission to bolus dosing or constant infusion, and usual daily outpatient dose (given intravenously) versus high dose (2.5 times their usual daily dose). No significant differences were noted in predefined outcomes between bolus and infusion administration. However, the high-dose group had better relief of dyspnea and more fluid and weight loss than the lower-dose group; also, 23% of the high-dose group had a significant deterioration in renal function, but at 60 days there was no difference in renal function between the two groups.⁵¹

An association between high-dose loop diuretics and a worse prognosis has been observed. There is concern that this may be mediated by further activation of the renin-angiotensin-aldosterone system by loop diuretics. However, in a retrospective analysis utilizing propensity matching, hospital mortality rate was not different between low-dose and high-dose diuretic groups.⁵² It is likely that poorer outcomes associated with high-dose diuretics is not due to the drug itself but reflects a greater severity of heart failure illness with concomitant renal disease.⁵³

Whatever initial dose of diuretic is chosen, subsequent dosing should be titrated to the response of the patient's fluid status and symptoms. Dosage reduction should be considered as the clinical status improves. Hypokalemia, alkalosis, and hypomagnesemia are frequent side effects of loop diuretics and can potentiate the occurrence of arrhythmias. Electrolyte levels must be carefully monitored during aggressive diuretic therapy.

Patients with chronic heart failure with or without renal dysfunction may exhibit resistance to loop diuretics, defined as an acute reduction in diuretic efficacy after repeated loop diuretic dosing. With chronic loop diuretic use, there is an increase in sodium reabsorption in the distal nephron and stimulation of aldosterone release. In edematous states there is delayed oral absorption of the drug. With renal dysfunction there may be reduced levels of drug delivered to the renal tubule. This resistance is associated with a poorer prognosis.²³ Diuretics that act distally in the renal tubule, such as metolazone or hydrochlorothiazide, or aldosterone blockers such as spironolactone can be added.⁴ Combination diuretic therapy induces a greater diuresis than simply increasing the dose of loop diuretic further. The response may be delayed for 48 to 72 hours. Combining diuretics often augments diuresis even in the setting of significant chronic kidney disease, and a good response can be expected in over 70% of patients. Particular attention must be given to following potassium, sodium, chloride, and magnesium levels when combination diuretic therapy is prescribed⁵⁴ (Table 29.4).

Table 29.4 Continuous Intravenous (IV) Infusion of Loop Diuretics

Diuretic	Dose
Bumetanide	1 mg IV load, then 0.5-2 mg/hr infusion
Furosemide	40 mg IV load, then 10-40 mg/hr infusion
Torsemide	20 mg IV load, then 5-20 mg/hr infusion

Adapted from Nieminen MS, Bohm M, Cowie MR, et al: Executive summary of the guidelines on the diagnosis and treatment of acute heart failure. The Task Force on Acute Heart Failure of the European Society of Cardiology. Eur Heart J 2005;26:384-416.

VASOPRESSIN INHIBITORS

The use of novel diuretics, vasopressin inhibitors, has been evaluated in clinical trials of treatment of acute heart failure.⁵⁵ Vasopressin is a hormone synthesized in the hypothalamus; its major effect is to control free water clearance. It acts through V1a receptors in vascular smooth muscle and myocardium, leading to peripheral and coronary vasoconstriction, myocyte hypertrophy, and positive inotropy. Vasopressin also acts through V2 receptors at the renal tubule collecting ducts to cause free water retention and hyponatremia. Levels of vasopressin are increased in patients with chronic heart failure, and higher vasopressin levels correlate with worse heart failure severity. Vasopressin release is stimulated by changes in serum osmolality and cardiac output and leads to further vasoconstriction and retention of free water.⁵⁶ Inhibition of vasopressin's effects would have theoretic benefits in patients with heart failure.⁵⁷ In contrast to loop diuretics, inhibition of vasopressin theoretically would not cause hypotension or neurohormonal activation, and would not aggravate cardiac arrhythmias due to electrolyte depletion.

Conivaptan is a vasopressin antagonist that inhibits V1a and V2 receptors. Tolvaptan and lixivaptan are antagonists selective for the V2 receptor. These medications increase urine volume and free water excretion, with a rise in the serum sodium concentration. The use of conivaptan in patients with class III-IV heart failure was associated with increased urine output, and decreases in PCWP and right atrial pressure, without changes in cardiac output.⁸ Oral use of tolvaptan was associated with fluid loss and diuresis without change in heart rate, blood pressure, or serum creatinine.

In a large, multicenter, placebo-controlled randomized trial called EVEREST, tolvaptan was administered to patients hospitalized with heart failure. There were no adverse consequences on heart rate, blood pressure, or serum electrolytes and there was more rapid improvement in dyspnea and signs of heart failure when compared to usual therapy.⁵⁸ Hyponatremia improved. Hemodynamic effects included rapid reduction in PCWP and right atrial pressure.⁵⁹ However, at 10-months follow-up after hospitalization, there was no improvement in mortality rates or readmission rates.⁶⁰ Vasopressin inhibitors are approved for treatment of severe hyponatremic states but are not approved for use in heart failure.

Table 29.5 Comparison of Hemodynamic Effects of Parenteral Vasodilators and Inotropic Agents

Hemodynamic Measure	Nitroprusside	Nesiritide	Dobutamine	Milrinone
Mechanism of action	Balanced vasodilator	Vasodilator, natriuretic	β_1 -Adrenergic receptor stimulator	Phosphodiesterase inhibitor
Heart rate	—	—	Slight \uparrow	Slight \uparrow
Arrhythmia	—	—	+	+
Mean right atrial pressure	\downarrow	\downarrow	\downarrow	$\downarrow\downarrow$
Left ventricular end-diastolic pressure	$\downarrow\downarrow$	$\downarrow\downarrow$	\downarrow	$\downarrow\downarrow$
Mean arterial pressure	\downarrow	\downarrow	—	\downarrow
Systemic vascular resistance	$\downarrow\downarrow$	$\downarrow\downarrow$	\downarrow	$\downarrow\downarrow$
Cardiac index	\uparrow	\uparrow	$\uparrow\uparrow$	$\uparrow\uparrow$
dP/dt (inotropy)	—	—	$\uparrow\uparrow$	\uparrow
Hypotension	+	+	Occasionally	+
Direct Na ⁺ excretion	—	+	—	—
Other considerations	Increased cyanide and thiocyanate levels with prolonged infusion	Serum B-natriuretic peptide level cannot be followed during infusion	Difficult to use in patients receiving long-term beta-blocker therapy	More vasodilator response at higher doses

—, minimal or no effect; +, positive effect; \uparrow or \downarrow , mild increase or decrease, respectively; $\uparrow\uparrow$ or $\downarrow\downarrow$, moderate increase or decrease, respectively.

PARENTERAL VASODILATORS (TABLE 29.5)

Intravenous vasodilator therapy is often added to diuretic therapy to obtain more rapid improvement in severe heart failure. A clear indication for vasodilators is in patients with severe hypertension and pulmonary edema. Their use should also be considered in patients who are not responding to intravenous diuretics combined with standard oral therapies. Blood pressure response to these medications needs to be carefully monitored because hypotension is a common effect. Improvement in hemodynamics has been obtained with aggressive intravenous vasodilator therapy using intravenous nitroprusside, intravenous nitroglycerin, or nesiritide. The choice of agents depends on matching the patient's clinical picture and hemodynamics with the predicted effects of each vasodilator.^{61,62}

NITROGLYCERIN

Intravenous nitroglycerin is an effective systemic and coronary vasodilator. It is very useful in heart failure due to acute coronary ischemia, as it improves coronary blood flow. Intravenous nitroglycerin lowers preload and PCWP, thereby reducing pulmonary congestion, without increasing oxygen demand. It is also an arterial dilator at high doses but is less effective at reducing afterload than nitroprusside. Dosage ranges between 5 and 200 $\mu\text{g}/\text{minute}$. A major limitation of the use of intravenous nitroglycerin is the rapid development of tolerance to the drug's effect, often occurring after only 24 hours of therapy. Prescribing a "nitrate-free" period during the daily dosage regimen has been advocated to limit the development of tolerance, but this option is not feasible in patients receiving parenteral therapy. Oral or topical nitrates may be added to chronic heart failure therapy with beta blockers and ACE inhibitors if blood pressure allows, but nitrates have not been shown to improve long-term prognosis.

NITROPRUSSIDE

Intravenous sodium nitroprusside is a powerful venous and arterial dilator. It is a drug of choice in treating hypertension-related heart failure with pulmonary edema and severe heart failure due to acute mitral regurgitation. The use of nitroprusside requires hospitalization in the ICU and invasive monitoring with a PA catheter and arterial line. This drug causes a significant reduction of afterload and preload, leading to decreased right atrial pressure, decreased systemic vascular resistance, decreased mean systemic blood pressure, decreased PCWP, and increased cardiac index in patients with heart failure and left ventricular dysfunction. Limitations of nitroprusside use include inducing a coronary "steal" syndrome in patients with active coronary ischemia.³⁹ In addition, toxic metabolites can accumulate with more prolonged administration. In patients with significant hepatic dysfunction, thiocyanate levels rise, and in patients with renal dysfunction, cyanide is generated. Dosage range is 0.3 to 5.0 $\mu\text{g}/\text{kg}/\text{minute}$.

NESIRITIDE (B-NATRIURETIC PEPTIDE)

Human BNP can be manufactured by recombinant DNA technology and is available as an intravenous medication, nesiritide, for heart failure therapy. BNP is a hormone produced by ventricular and atrial myocytes in response to stretch from cardiac chamber dilatation. Hemodynamic effects include venous and arterial dilation, coronary vasodilation, and natriuresis. Reduction in PCWP and right atrial pressure exceeding the effects of intravenous nitroglycerin, when compared directly, was reported.⁶¹ It is not proarrhythmic and does not induce tolerance.⁶³ It may potentiate the effects of loop diuretics. Significant hypotension may limit its use in some patients.³⁹ Because the hypotensive effects of nesiritide are less marked than nitroprusside, nesiritide can be used without invasive hemodynamic

monitoring and can be initiated in emergency department settings. Nesiritide is initiated as an intravenous bolus dose of 2 µg/kg followed by infusion of 0.01 µg/kg/minute.

Nesiritide was compared to dobutamine in patients with severe heart failure. Nesiritide infusion was associated with less tachycardia and ventricular arrhythmia.⁶⁴ Other non-randomized studies suggested a trend toward improved survival and lower rehospitalization rates with nesiritide.⁶³ A meta-analysis of three randomized trials of nesiritide suggested a slight increase in mortality rates in patients given nesiritide versus a placebo control group, possibly mediated through an adverse effect on renal function.^{65,66} A retrospective review of patients receiving intravenous vasoactive medications for acute heart failure indicated mortality rates, adjusted for clinical variables, were equivalent for patients receiving nitroglycerin or nesiritide. Patients who received intravenous nesiritide or intravenous nitroglycerin had a lower in-hospital mortality rate compared with patients who received dobutamine or milrinone.⁶⁷

In view of these conflicting results of retrospective analyses, a randomized, placebo-controlled international study, called ASCEND-HF, was performed to evaluate the effect of nesiritide on relief of dyspnea, mortality rate, and renal function in patients hospitalized with acute heart failure; 7141 patients were enrolled. Over 90% of patients received loop diuretics and 15% received vasodilator therapy. Patients who received nesiritide had slightly better relief of dyspnea at 6 and 24 hours, although this did not meet a prespecified significant improvement in dyspnea score. There was no significant difference in hospital mortality rates, 30-day mortality rate, or death or rehospitalization at 30 days. There was no significant worsening of renal function in the nesiritide group. Hypotension was significantly more common in the nesiritide group (26.6%) compared with control group (15.3%). The authors concluded that nesiritide was not useful for routine use in the management of patients with severe heart failure.⁶⁸

Nesiritide should be used only in patients admitted to hospital with acute decompensated heart failure, to relieve dyspnea at rest when more conventional therapies have proved to be ineffective. This medication should not be used to replace diuretics, to enhance renal function, or to improve diuresis. It should not be used as an intermittent infusion in an outpatient setting.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors are of limited use as parenteral therapy in patients with acute severe heart failure in the urgent setting. Enalaprilat is an intravenous bolus formulation that can be used in patients with chronic heart failure who are taking chronic oral ACE inhibitor therapy and who are unable to take oral medication. The maximal action occurs 1 to 4 hours after administration, with a 6-hour duration of action.

INOTROPIC DRUGS (SEE TABLE 29.5)

DOBUTAMINE

Dobutamine is a potent β_1 -agonist. It also has β_2 - and α -agonist properties. Its major effects are increased

myocardial contractility and increased cardiac output. It increases myocardial oxygen demand. It also has venodilator properties. At doses of 2.5 to 15 µg/kg/minute, dobutamine will lower systemic vascular resistance and PCWP and cause a slight increase in heart rate. Higher doses are associated with vasoconstriction.

In patients with heart failure, β -receptors may be chronically downregulated. Therefore, the effects of dobutamine may be attenuated in chronic heart failure patients. Dobutamine may be detrimental in patients with active coronary ischemia or following myocardial infarction due to increased myocardial oxygen demand and oxygen consumption. Ventricular arrhythmias are associated with dobutamine use.⁶⁴ Tolerance to the effects of dobutamine has been demonstrated in patients with infusions lasting more than 24 hours, due theoretically to induction of β -receptor downregulation.⁶⁹

MILRINONE

Milrinone is an inhibitor of myocyte phosphodiesterase. This leads to increased intracellular cyclic adenosine monophosphate and calcium. It is an inotropic agent that acts “downstream” from the β -receptor. Hemodynamic effects include reduction of right atrial pressure and reduction in pulmonary and systemic vascular resistance. In heart failure, stroke volume and cardiac output are increased with a slight fall in mean systemic arterial pressure. Milrinone acts as a coronary vasodilator, and there is no net increase in myocardial oxygen consumption. Arterial blood pressure and PCWP tend to be lowered more than with dobutamine, and milrinone’s action is more prolonged. There is no tolerance or attenuation of its effect. Milrinone is started as a bolus dose 50 to 75 µg/kg, with a maintenance infusion of 0.375 to 0.75 µg/kg/minute. Doses need to be reduced in patients with renal failure. Its use is limited in patients with hypotension.

CONSIDERATIONS REGARDING THE USE OF INOTROPES

Inotropic drugs are used in patients with reduced LV systolic function and low cardiac output with persistent symptomatic hypotension and signs of end-organ hypoperfusion or cardiogenic shock. Clinically, this is often manifest as systolic blood pressure less than 90 mm Hg, narrow pulse pressure, cool and clammy extremities, anorexia, obtundation, and oliguria. Hemodynamic findings that may lead to use of inotropes include cardiac index less than 2.0 L/minute/m², PCWP greater than 20 mm Hg, and right atrial pressure greater than 10 mm Hg.⁷⁰

The choice of milrinone versus dobutamine depends on the specific clinical circumstances.⁷¹ Dobutamine tends to cause a slight rise in heart rate and has little effect on mean arterial pressure, whereas milrinone often lowers systemic arterial pressure due to more prominent lowering of systemic vascular resistance.^{72,73} Patients who do not respond to dobutamine may have a favorable response to milrinone. In the setting of acute heart failure, milrinone is used more often than dobutamine in view of its more potent vasodilator properties. In addition, its effects are not primarily mediated through β -receptors, which is an important consideration in patients receiving concomitant beta-blocker therapy. However, dobutamine has a much shorter half-life

than milrinone, so dobutamine-induced hypotension can be more rapidly reversed by discontinuing the drug, making dobutamine a somewhat safer drug in the acute setting. Several studies have been done evaluating the usefulness of routine inotropic therapy, comparing milrinone or dobutamine with placebo. The consistent conclusion has been that inotropic agents are not useful for routine use in patients with decompensated heart failure, and in fact may worsen short-term prognosis. The use of a 48-hour infusion of milrinone was evaluated as routine therapy in patients admitted with class III-IV heart failure, when inotropic therapy was not felt to be essential. When compared to standard therapy without milrinone, no improvement in symptom relief, hospital length of stay, or rehospitalization rate within 60 days was demonstrated.⁷⁴ Milrinone was associated with an increased incidence of hypotension and atrial arrhythmias. In the FIRST study of class III-IV heart failure patients, an average 14-day infusion of dobutamine was associated with an *increased* risk of morbid events and higher short-term mortality rates.⁷⁵ No clinical studies have shown improved short-term or medium-term outcomes with inotropic therapy. The use of inotropic agents has been consistently associated with a *worse* prognosis for survival.³⁹ These negative outcomes with inotropic agents are felt to be related to their propensity to stimulate sympathetic nervous system activation, increasing myocardial oxygen demand, exacerbating serious cardiac arrhythmias, increasing myocardial ischemia, and furthering myocyte loss. Stimulation of chronic hibernating myocardium may also result in myonecrosis.

If use of an inotrope is necessary, the shortest duration of therapy should be attempted (i.e., less than 72 hours). Current ACC/AHA Guidelines for evaluation and management of chronic heart failure indicate that long-term intermittent infusions of a positive inotropic drug as therapy for symptomatic systolic dysfunction is *contraindicated*.⁴ Continuous intravenous infusion of an inotropic drug can be used as a bridge to therapy with mechanical circulatory assist devices or cardiac transplantation. Continuous inotrope infusion can also be recommended for palliation of symptoms in patients with refractory end-stage heart failure (stage D). These patients will have been deemed poor candidates for more advanced therapies. In this setting, quality of remaining life takes precedence over prolonging life. In one report of patients with refractory end-stage heart failure, median survival of patient on continuous inotrope infusion was 3.4 months, with 26% of patients surviving to 6 months.⁷⁶ The decision to use inotropic agents in this circumstance is one that should be carefully individualized.

VASOPRESSORS

DOPAMINE

Dopamine effects include increased renal blood flow (at low doses, 1-5 µg/kg/minute), increased myocardial contractility and chronotropy through stimulation of β-receptors (doses of 3-7 µg/kg/minute), and vasoconstriction at higher doses (5-20 µg/kg/minute). Dopamine is a less useful agent for treatment of heart failure because its effects result in tachycardia, coronary vasoconstriction, increased afterload, and increased oxygen consumption. Dobutamine generally will lead to a greater rise in cardiac output than dopamine.

Dopamine can be used when significant hypotension is part of the hemodynamic picture, when it is necessary to restore adequate arterial pressure for end-organ perfusion. Although dopamine at low doses is frequently used as add-on therapy to inotropic agents in an attempt to increase renal blood flow and augment diuresis, no controlled trials have demonstrated dopamine's usefulness in this setting. No significant benefit of "renal dose dopamine" has been shown in preventing acute renal failure in high-risk patients or in the treatment of established renal failure.⁶⁹

NOREPINEPHRINE

Norepinephrine is a sympathomimetic agent with strong α-agonist and weak β-agonist effects. In patients with heart failure, norepinephrine's main effect is to raise blood pressure by increasing systemic vascular resistance with little effect on cardiac output. It will increase myocardial oxygen demand. Its use in the setting of heart failure is restricted to patients with the most severe hypotension, unresponsive to dopamine, or in patients with complicating illnesses such as sepsis.⁶⁹ Norepinephrine should be weaned and discontinued as early as possible. Dosage range is 0.2 to 1 µg/kg/minute.

Norepinephrine and dopamine were compared in a randomized controlled trial of 1679 patients with shock, 280 (16.7%) of whom had cardiogenic shock. In the entire group, there was no difference in survival at 28 days if patients were treated with norepinephrine or dopamine. However, in the subgroup with cardiogenic shock (a pre-defined subgroup analysis), dopamine use was associated with a significantly increased mortality rate. In addition, in the entire group, dopamine was associated with significantly higher rates of arrhythmia (24% versus 12.4% with norepinephrine), especially atrial fibrillation, which led to stopping the vasopressor more frequently. There was also a higher rate of severe arrhythmia with dopamine (6.1%) compared with norepinephrine (1.6%).⁷⁷ Based on the results of this study, norepinephrine is the preferred vasopressor in patients with cardiogenic shock.

An algorithm for the approach to the evaluation and therapy of acute heart failure is presented in [Figure 29.3](#).

ULTRAFILTRATION

A new approach to the treatment of acute heart failure is venovenous ultrafiltration. This process removes iso-osmolar extracellular fluid via a convection process and is not associated with changes in serum electrolytes.⁷⁸ Anticoagulation is utilized during the process. Newer ultrafiltration systems utilize peripheral arm veins, and central venous access is not required. In a study of 40 patients admitted with heart failure, usual care for heart failure with diuretic therapy was compared with usual care combined with ultrafiltration. At 24 hours, average fluid loss with diuretic therapy was 2838 mL, compared with 4650 mL with ultrafiltration. Weight loss and improvement in dyspnea was similar with the two therapies. Ultrafiltration was not associated with significant changes in heart rate or blood pressure.⁷⁹ In another study, 20 patients with acute decompensated heart failure with renal insufficiency and diuretic resistance were treated with an 8-hour course of ultrafiltration. Over 24 hours, an average of 8650 mL of fluid was removed, with an

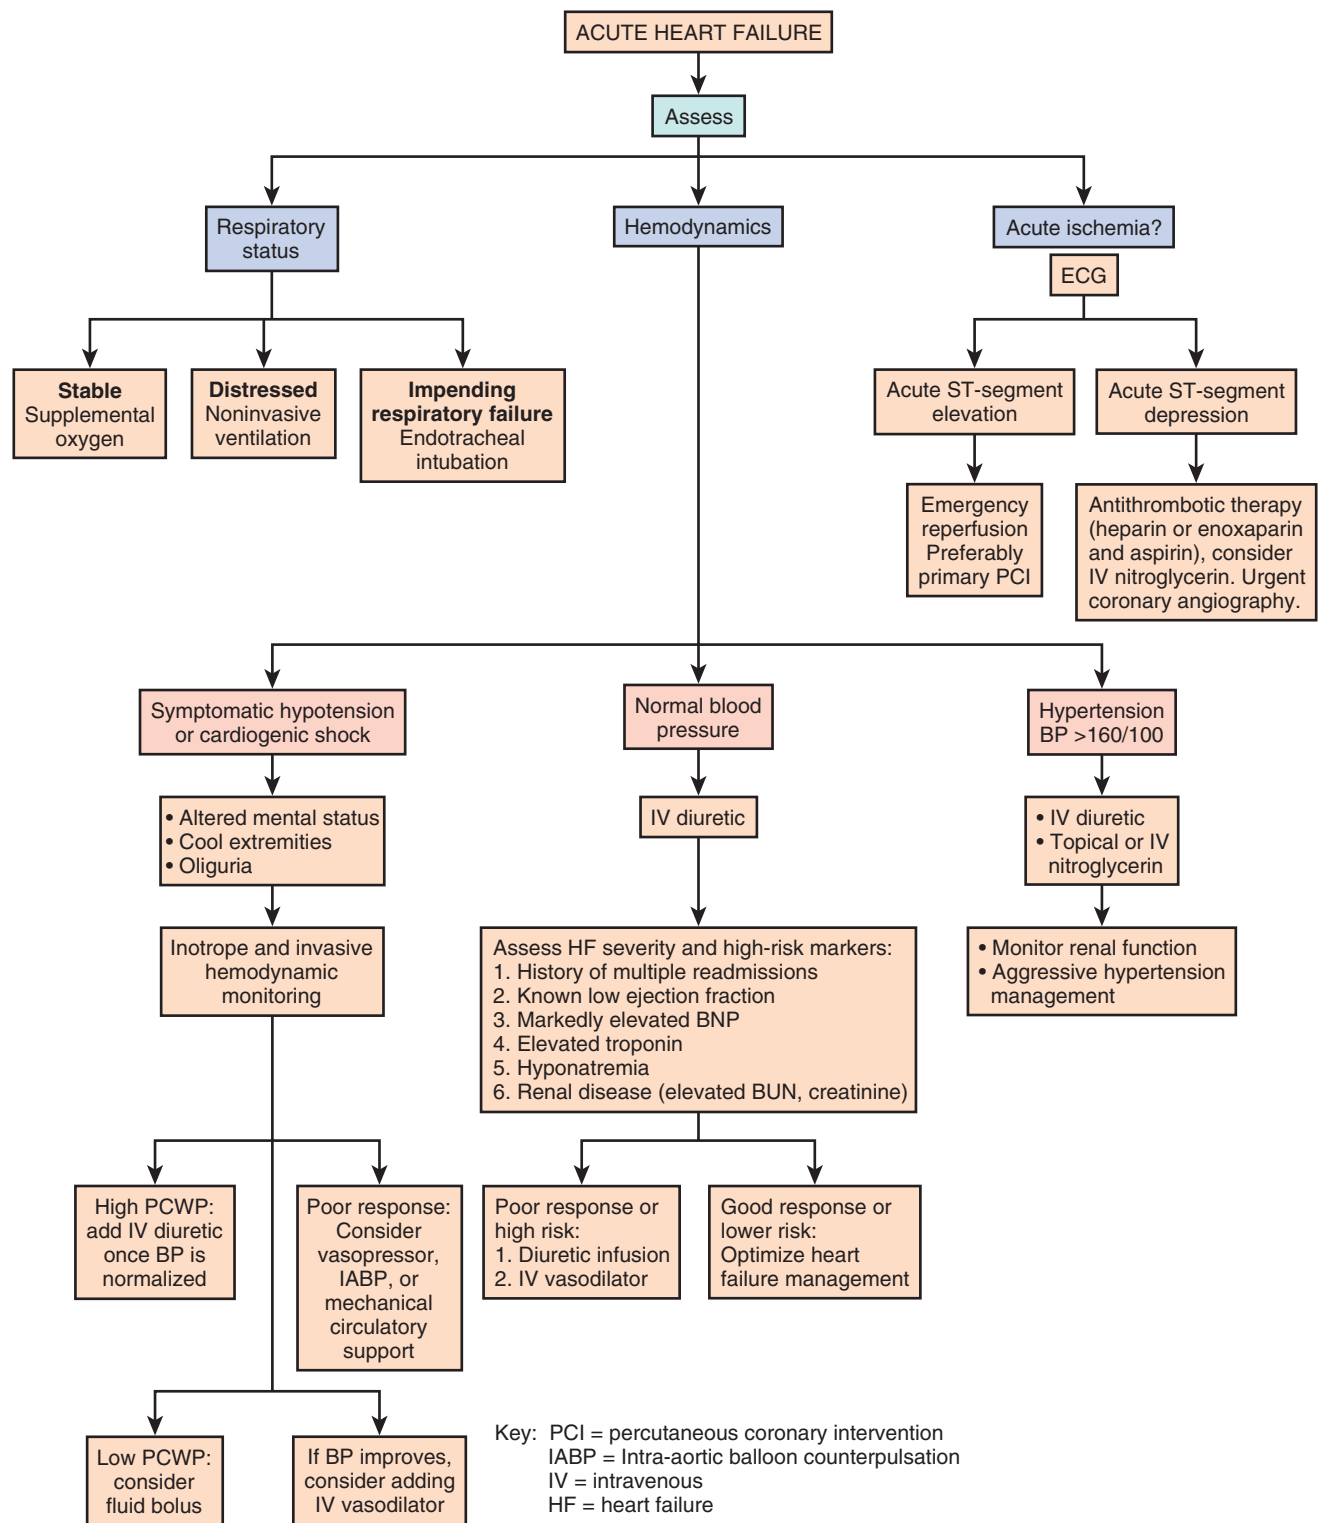

Figure 29.3 Algorithm for the treatment of acute heart failure. (Adapted from Pang PS: Acute heart failure syndromes. *Emerg Med Clin North Am* 2011;29:675-688.)

average weight loss of 6 kg during hospitalization. Renal function remained stable, and there was no associated hypotension.⁷⁸

The UNLOAD trial investigated the use of ultrafiltration compared to intravenous diuretic therapy in 200 patients admitted with acute decompensated heart failure. Ultrafiltration was associated with more rapid weight loss and fluid

loss. At 90 days, there were fewer rehospitalizations for heart failure in the ultrafiltration group, without change in mortality rates. There was no difference with respect to renal function in the two groups.⁸⁰

A trial was conducted that compared ultrafiltration with standard intravenous diuretic therapy in patients admitted to hospital with acute decompensated heart failure,

persistent congestion, and worsening renal function. Fluid was removed with UF at a rate of 200 mL per hour. This trial showed worse outcomes with ultrafiltration at 96 hours of therapy. Renal function worsened with UF and did not with diuretics. Total weight loss was unchanged between the two groups. Serious adverse effects were more common in the UF group, mainly renal failure, bleeding, and catheter-related complications. There was no difference between the two groups in symptom relief, mortality, or rehospitalization at 60 days.^{80a} At this time, ultrafiltration is reserved for the relief of severe congestion in patients who are refractory to aggressive diuretic therapy and should not be used to replace diuretics.⁸¹ Further studies will determine if this therapy should be used more routinely in the management of acute heart failure.

TRANSITION TO CHRONIC PHARMACOLOGIC THERAPY FOR SEVERE HEART FAILURE

The medical treatment of chronic systolic heart failure is based on results of many large, randomized, placebo-controlled trials (see later) and is indicated for almost all causes of chronic left ventricular dysfunction. Pharmacologic agents should be started when left ventricular dysfunction is first diagnosed. Therapy is aimed at optimizing fluid balance and reversing the neurohormonal activation responsible for left ventricular remodeling and progressive decline in left ventricular function.⁸² Long-term prognosis is directly related to the process of “reverse remodeling.”

After patients have improved with acute therapies, medical treatments are instituted to address the long-term goals of improvements in functional status, exercise tolerance, and survival. Standard drug regimens combine several classes of medication, all of which have been shown in large, randomized controlled trials to reduce mortality rate, reduce the rate of rehospitalization, and decrease the risk of sudden arrhythmic death. Doses of these medications are optimized during hospitalization. Chronic adherence with these medications is more consistent when they are initiated in-hospital.

DIURETICS

Loop diuretics are routinely used in patients with signs or symptoms of fluid retention.⁴ Diuretics are continued once patients are euvolemic to prevent reaccumulation of fluid. A flexible dosing schedule, based on daily weights and close telephone contact with a heart failure treatment team member, can be very effective in maintaining a euvolemic state while reducing the frequency of side effects.

Furosemide is the most common loop diuretic used. Bumetanide or torsemide may be helpful in patients with suboptimal responses to furosemide, due to their more consistent absorption after oral administration. Metolazone or a thiazide diuretic can be used in addition to a loop diuretic in patients with more severe heart failure due to their synergistic effects. Patients must be periodically monitored for side effects of these agents including azotemia, hypokalemia, alkalosis, hyponatremia, and hypomagnesemia (Table 29.6).

Table 29.6 Oral Diuretics Recommended for Use in the Treatment of Fluid Retention in Chronic Heart Failure

Drug	Initial Daily Dose(s)	Maximum Total Daily Dose	Duration of Action
Loop Diuretics			
Bumetanide	0.5-1.0 mg once or twice	10 mg	4-6 hours
Furosemide	20-40 mg once or twice	600 mg	6-8 hours
Torsemide	10-20 mg once	200 mg	12-16 hours
Thiazide Diuretics			
Chlorothiazide	250-500 mg once or twice	1000 mg	6-12 hours
Chlorthalidone	12.5-25 mg once	100 mg	24-72 hours
Hydrochlorothiazide	25 mg once or twice	200 mg	6-12 hours
Indapamide	2.5 mg once	5 mg	36 hours
Metolazone	2.5 mg once	20 mg	12-24 hours
Potassium-Sparing Diuretics			
Eplerenone	12.5 mg once	20 mg	24 hours
Spironolactone	12.5-25 mg once	50 mg*	2-3 days
Triamterene	50-75 mg once	200 mg	7-9 hours

*Higher doses may occasionally be used with close monitoring of serum creatinine and potassium levels.

A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society of Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation* 2005;112:1825-1852.

Table 29.7 Inhibitors of the Renin-Aldosterone System and Beta Blockers Commonly Used for the Treatment of Patients with Heart Failure and Low Ejection Fraction

Drug	Initial Daily Dose(s)	Maximum Dose(s)
Angiotensin-Converting Enzyme Inhibitors		
Captopril	6.25 mg 3 times	50 mg 3 times
Enalapril	2.5 mg twice	10-20 mg twice
Fosinopril	5-10 mg once	40 mg once
Lisinopril	2.5-5 mg once	20-40 mg once
Perindopril	2 mg once	8-16 mg once
Quinapril	5 mg twice	20 mg twice
Ramipril	1.25-2.5 mg once	10 mg once
Trandolapril	1 mg once	4 mg once
Angiotensin Receptor Blockers		
Candesartan	4-8 mg once	32 mg once
Losartan	25-50 mg once	50-100 mg once
Valsartan	20-40 mg twice	160 mg twice
Aldosterone Antagonists		
Spironolactone	12.5-25 mg once	25 mg once or twice
Eplerenone	25 mg once	50 mg once
Beta blockers		
Bisoprolol	1.25 mg once	10 mg once
Carvedilol	3.125 mg twice	25 mg twice (50 mg twice for patients weighing >85 kg)
Metoprolol succinate extended-release	12.5-25 mg once	200 mg once

A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society of Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation* 2005;112:1825-1852.

BETA BLOCKERS (TABLE 29.7)

Catecholamine levels are increased in heart failure, and higher levels correlate with worse disease severity. Catecholamines have direct negative effects on the myocardium including induction of myocyte hypertrophy and apoptosis.¹³ Clinically, these effects are evident as left ventricular dilatation, increased ischemia, increased peripheral vasoconstriction, and cardiac arrhythmia.

Beta blockers interfere with catecholamine-mediated activation of cardiac β -receptors and thereby attenuate β -receptor-mediated increases in heart rate and oxygen

Figure 29.4 All-cause mortality rate in patients with class III to class IV heart failure, ejection fraction less than 25%, demonstrating significant survival benefit with carvedilol. (Redrawn from Packer M, Coats A, Fowler M, et al: Effect of carvedilol on survival in severe chronic heart failure. *N Engl J Med* 2001;344:1651-1658.)

consumption. Sympathetic nervous system-mediated effects on remodeling can be prevented or attenuated. In addition, carvedilol blocks β -receptors and also α -receptors, which mediate vasoconstriction and increased cardiac contractility.

Multiple large trials using beta blockers in thousands of patients with chronic heart failure, or in post-myocardial infarction patients with ejection fractions below 40%, have demonstrated significant and consistent reductions in the need for repeat rehospitalization for heart failure. Mortality rates are also significantly improved. The BHAT study showed a relative 26% reduction in mortality rates at 2 years in post-myocardial infarction patients treated with propranolol.^{83,84} The CIBIS II trial using bisoprolol showed a 34% relative risk reduction in hospitalizations and mortality rates at 16 months of therapy.⁸⁵ The MERIT-HF study showed a relative reduction of 33% in these end points at 12 months using metoprolol succinate.⁸⁶ Patients with more severe heart failure, symptom class III-IV, with severely reduced ejection fractions below 25% were studied in the COPERNICUS trial. These patients began therapy with carvedilol during hospitalization. At mean follow-up of 10.4 months, a 35% relative mortality rate reduction was seen, with improvement in mortality rates beginning as early as 3 weeks after initiation of therapy⁸⁷ (Fig. 29.4). In these trials, beta blockers were not discontinued more frequently than placebo for perceived side effects, and there was no increased risk of heart failure exacerbation due to beta-blocker therapy when compared to placebo, even in the early phases of drug administration.⁸⁸ Several trials with carvedilol have shown an approximate 6% absolute increase in left ventricular ejection fraction after a minimum of 2 years of therapy.⁸⁹

Beta blockers should be started for treatment of heart failure and left ventricular dysfunction when patients are stable. Beta blockers should be instituted early, once patients are deemed euvoletic, and titrated up to maximal

recommended doses (e.g., metoprolol succinate 200 mg daily or carvedilol 25 mg twice daily) or maximally tolerated doses. They are useful in patients with ischemic and nonischemic cardiomyopathy. Beta blockers should be instituted in patients who appear compensated and stable off this medication, as these patients have a high likelihood of disease progression to symptomatic heart failure within 12 months. Beta blockers are recommended for left ventricular dysfunction even in the absence of symptoms (stage B patients). This therapy should be combined with other recommended heart failure pharmacologic therapy. Contraindications to beta-blocker use include severe bradycardia or bronchospastic lung disease.

For patients who are already taking beta-blocker therapy and who are hospitalized with acute decompensation of heart failure, beta blockers should be continued. Withdrawal of this medication was associated with higher short-term mortality rates and more frequent rehospitalizations for heart failure in several observational studies.⁹⁰ In patients with a severe heart failure exacerbation, reduction of the chronic dose by 50% can be considered. Beta blockers should only be stopped in the presence of symptomatic hypotension, cardiogenic shock, severe bradycardia, or heart block. If beta blockers are temporarily withheld, they should be reinstituted prior to discharge unless there are ongoing specific contraindications.^{91,92}

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS (SEE TABLE 29.7)

These agents act to counteract the effects of activation of the renin-angiotensin system by blocking the conversion of angiotensin I to angiotensin II, inhibiting the deleterious effects of angiotensin II and aldosterone. Many studies have shown benefits of ACE inhibitor therapy in post-myocardial infarction patients as well as patients with cardiomyopathy and heart failure. The SOLVD trial using enalapril in patients with class II-III heart failure and ejection fractions below 35% showed a 10% relative risk reduction in mortality rate at 3.5 years.⁹³ Enalapril given to patients less ill, with asymptomatic left ventricular dysfunction (ejection fractions under 35%) in the companion SOLVD trial showed a reduction in the clinical diagnosis of heart failure and a statistically significant reduction in heart failure hospitalizations at 3 years.⁹⁴ A meta-analysis performed of 32 trials involving 7105 patients, using captopril, enalapril, ramipril, quinapril, or lisinopril, found that ACE inhibitors reduce the risk of death and hospitalization due to heart failure.⁹⁵ These results indicate that the positive effects of ACE inhibitors are likely to be a class effect, and not specific to a particular agent.

Side effects of these agents include cough, worsening renal function in patients with underlying renal disease or renal artery stenosis, angioneurotic edema, and hyperkalemia. The dose of ACE inhibitors should be increased as renal function and blood pressure allow. Studies have shown that medium doses of ACE inhibitors, when compared to low doses, significantly reduce hospitalization rates for heart failure. However, higher doses given routinely do not significantly reduce cardiovascular events further.⁹⁶ Additional improvement in symptoms and mortality rates is thus best achieved by adding on beta blocker and other

heart failure therapy rather than increasing ACE inhibitors to the highest doses.⁹⁷

In a study of class II-III chronic heart failure patients over age 65, with an ejection fraction of less than 35%, the importance of first beginning heart failure therapy with an ACE inhibitor or a beta blocker was studied. The primary end point was time to death or hospitalization for heart failure. Initiation of the beta blocker bisoprolol was not inferior to the strategy of starting therapy with the ACE inhibitor enalapril. There was also no difference in safety.⁹⁸

ANGIOTENSIN RECEPTOR BLOCKERS (SEE TABLE 29.7)

Angiotensin receptor blockers (ARBs) work to counter the effects of angiotensin II at the tissue level by blocking angiotensin II receptors. Multiple studies have shown benefits of these medications in patients with heart failure. Large numbers of patients in controlled trials have been studied, and these drugs have been as well studied as the ACE inhibitors. ARBs have been used as a substitute for ACE inhibitors or given in combination with ACE inhibitors and beta blockers.

The RESOLVD trial, using candesartan in heart failure patients with a mean ejection fraction of 27%, showed equivalent mortality rates and similar exercise tolerance and functional class to patients treated with enalapril at 3.5 years.⁹⁹ ELITE II, a study using losartan compared with captopril in patients with ejection fractions under 40%, showed no difference in mortality rates or congestive heart failure admissions. Losartan was better tolerated because of the lower incidence of problematic cough.¹⁰⁰ The ValHeft 2001 trial showed that valsartan as a substitute for ACE inhibitor therapy was associated with a relative 33% risk reduction in mortality rate when compared with placebo.¹⁰¹ In CHARM, candesartan was prescribed for patients with ejection fractions under 40%. A 17.5% relative risk reduction in cardiovascular death and congestive heart failure admissions was seen when this ARB was used as a substitute for ACE inhibitors.¹⁰² When candesartan was added to therapy with ACE inhibitors and beta blockers, a small 10% relative risk reduction was seen, without increased mortality rates.¹⁰³

ARBs are an appropriate choice for patients who cannot be maintained on ACE inhibitors because of side effects such as cough. Patients with angioneurotic edema during ACE inhibitor therapy have often been successfully treated with ARBs without developing this complication.^{104,105} Adding ARB therapy onto ACE inhibitors and beta blockers may achieve a small additional benefit, at the risk of more renal dysfunction and hyperkalemia.

ALDOSTERONE ANTAGONISTS (SEE TABLE 29.7)

Aldosterone antagonists counteract the salt and water retention caused by aldosterone. In addition, aldosterone is felt to be involved in the progressive myocardial fibrosis that occurs as part of the remodeling process. In the RALES trial, the aldosterone antagonist spironolactone was given to patients with severe, class III-IV heart failure with ejection fraction below 35%. A 24% relative risk reduction in mortality was seen in treated patients over 2 years, with reduced cardiovascular death and reduced need for rehospitalization¹⁰⁶ (Fig. 29.5). Thus, these agents are effective at

Figure 29.5 Kaplan-Meier analysis of the probability of survival among patients in the placebo group and patients in the spironolactone group, treated for class III to class IV heart failure and left ventricular dysfunction. The risk of death was 30% lower among patients in the spironolactone group than among patients in the placebo group ($P < 0.001$). (Redrawn from Pitt B, Zannad F, Remme W, et al: The effect of spironolactone on morbidity and mortality in patients with severe heart failure. *N Engl J Med* 1999;341:709-717.)

No. at Risk

Placebo	841	775	723	678	628	592	565	483	379	280	179	92	36
Spironolactone	822	766	739	698	669	639	608	526	419	316	193	122	43

improving outcomes in patients with the most severe chronic heart failure. Aldosterone antagonists are contraindicated in patients with renal insufficiency and creatinine levels over 2.5 mg/dL (or GFR under 30 mL/minute) or in patients with baseline potassium levels over 5.0 mmol/L. Spironolactone should be initiated at low doses, such as 12.5 mg daily or every other day, especially in elderly patients.

An analysis of a large Canadian health care database showed a substantial increase in the frequency of spironolactone use after the RALES study was published. This increased use was temporally associated with a two- to three-fold increased rate of hospitalization for hyperkalemia.¹⁰⁷ This highlights the need for careful monitoring of serum electrolytes after aldosterone blockers are initiated.

Eplerenone is an aldosterone blocker similar to spironolactone except that it has less antiandrogen effects and thus is free of the side effect of gynecomastia in men. It has been found to be effective in treating heart failure following acute myocardial infarction (see later). More recently, it was also found to be very effective in patients with chronic heart failure. In EMPHASIS-HF, a placebo-controlled randomized study of 2737 patients with LV ejection fraction below 35% and class II heart failure, eplerenone was added to therapy with ACE inhibitors and beta blockers, at a target dose of 25 to 50 mg daily. Mean follow-up was 21 months. Eplerenone reduced the occurrence of the primary end point of cardiovascular death plus hospitalization for heart failure from 25.9% to 18.3% ($P < 0.001$), and with improvement in other clinical end points. Serious hyperkalemia that necessitated drug discontinuation occurred in only 1.1% of patients.¹⁰⁸

Aldosterone blockade appears to result in beneficial effects in heart failure independent of its potassium sparing and diuretic effects.¹⁰⁹ Aldosterone blockers are an important therapy for heart failure and should be routinely added

to ACE inhibitors and beta blockers in patients with symptomatic heart failure with low left ventricular ejection fraction.

COMBINATION HYDRALAZINE/ ISOSORBIDE DINITRATE

Combination therapy with the vasodilators hydralazine and isosorbide dinitrate (ISDN) was associated with improvement in mortality rate when compared to placebo in one study in the era prior to the advent of ACE inhibitors and beta-blocker therapy for heart failure.¹¹⁰ A retrospective analysis of this study suggested that African-American patients may have benefited preferentially. To evaluate this finding prospectively, the A-Heft study enrolled over 1000 self-described African-American patients with class II-IV heart failure and ejection fractions below 45%. The use of the combination of hydralazine with ISDN, titrated to a dose of 75 mg hydralazine plus 40 mg ISDN given three times daily, was associated with a 40% relative risk reduction in mortality at 10 months and a 33% relative risk reduction in first hospitalization for heart failure. This therapy was added on to treatment with beta blockers, ACE inhibitors, and spironolactone.¹¹¹ Hydralazine-ISDN is approved for treatment of African-American patients with heart failure and left ventricular systolic dysfunction.

DIGOXIN

Digoxin works by inhibiting the myocyte sodium-potassium pump, leading to increased intracellular calcium levels and increased inotropy. It also has vagotonic effects. However, digoxin is a relatively weak inotropic agent. The use of digoxin in heart failure was studied in large numbers of patients in the Digitalis Investigation Group (DIG) trial. A

decreased need for rehospitalization for heart failure was seen with this therapy. However, there was no improvement in overall mortality rate.¹¹² A post-hoc analysis of this data concluded that patients with lower serum digoxin levels (0.5-0.9 ng/dL) did have lower mortality rates and lower rates of heart failure hospitalization when compared to those with levels greater than 0.9 ng/mL.¹¹³

Digoxin is indicated only for patients with symptomatic heart failure, stages C and D.⁴ It is also useful in heart failure patients with atrial fibrillation to help control the ventricular rate. Digoxin is not useful in the setting of acute heart failure, and it should be avoided in patients with hypokalemia, bradycardia, or heart block.

CORONARY HEART DISEASE AND HEART FAILURE: SPECIAL CONSIDERATIONS

Coronary artery disease can lead to acute heart failure via several different mechanisms. Acute ischemia leads to impaired myocardial relaxation, acute diastolic dysfunction, and sudden elevation of left ventricular filling pressure. Acute ischemia can also cause “stunning,” defined as myocardial dysfunction due to severe and prolonged ischemia without infarction, which may persist for days or weeks after normal blood flow is restored but which eventually recovers function. Acute myocardial infarction may cause myocardial necrosis and acute left ventricular systolic dysfunction due to loss of contractile tissue. Papillary muscle ischemia, infarction, and rupture result in acute, severe mitral regurgitation and acute heart failure. Infarction, necrosis, and rupture of the intraventricular septum result in left-to-right shunting and acute heart failure with cardiogenic shock. Chronic ischemia can cause myocardial dysfunction and systolic heart failure without infarction, a process termed “hibernation.” Often, acute myocardial ischemia is superimposed on a ventricle impaired by chronic ischemia and infarction, so multiple mechanisms are usually present in patients with chronic coronary disease presenting with acute heart failure.^{23,114}

In a European observational study of acute heart failure complicating acute coronary syndromes (ACS) in patients without previous history of heart failure, 13% of ACS patients presented with heart failure on admission.¹¹⁵ Heart failure developed later during hospitalization in an additional 5.6% of patients. The incidence of acute heart failure of 15.6% was identical in patients with ST-segment elevation myocardial infarction and non-ST-segment elevation myocardial infarction. Eight percent of patients with unstable angina developed heart failure. Prognosis for these patients was poor, with in-hospital mortality rates of 12% for patients with heart failure on admission and 17.8% if heart failure developed during the hospitalization. This represents a three- to fourfold increase in mortality rates compared with patients with ACS without heart failure.

Several important points need to be stressed regarding acute heart failure and ACS. Acute heart failure may develop even without evidence of significant left ventricular systolic dysfunction on echocardiography and without acute necrosis documented by myocardial enzyme determinations. The majority of patients with ACS and heart failure do not have left ventricular systolic dysfunction at discharge, and only a

minority of these patients develop chronic heart failure. These patients not only have high in-hospital mortality rates but also have a high rate of morbidity and mortality after discharge, with 8.5% additional mortality rate at 6 months and 6-month rehospitalization rate of 24%.¹¹⁴

Early aggressive pharmacologic and interventional reperfusion strategies are indicated and should always be considered in these patients. Acute treatment should include intravenous diuretics, intravenous nitroglycerin, and beta-blocker therapy. Intra-aortic balloon counterpulsation should be used in patients with signs and symptoms of continued ischemia despite aggressive medical therapies or who have cardiogenic shock. Urgent coronary angiography is indicated to determine the most appropriate reperfusion strategy.¹¹⁴

ACUTE HEART FAILURE FOLLOWING MYOCARDIAL INFARCTION

In a large registry of 5573 consecutive patients with acute myocardial infarction, 42% of patients had heart failure or left ventricular systolic dysfunction during hospitalization.¹¹⁶ These patients tended to be older, were more commonly women, and were more likely to have had previous myocardial infarction or coronary bypass surgery. Comorbid conditions were present more commonly, including peripheral arterial disease, hypertension, diabetes mellitus, or previous stroke. In-hospital mortality rate for these patients was 13%, versus 2.3% for patients with acute myocardial infarction but without heart failure or left ventricular dysfunction. Mortality rate ranged 13% to 21% for patients with lung congestion and left ventricular ejection fraction below 40%. Other complications also occurred more commonly in these patients, including atrial and ventricular arrhythmias, reinfarction, and stroke (Figs. 29.6 and 29.7).

Figure 29.6 In-hospital mortality rate in patients admitted with acute myocardial infarction, according to presence of heart failure and left ventricular (LV) ejection fraction. EF, ejection fraction; HF, heart failure; Killip class I, patients without evidence of heart failure on physical examination; Killip class II, patients with evidence of heart failure on physical examination; LVSD, LV systolic dysfunction. (Redrawn from Velazquez EJ, Francis GS, Armstrong PW, et al: An international perspective on heart failure and left ventricular systolic dysfunction complicating myocardial infarction: The VALIANT Registry. *Eur Heart J* 2004;25:1911-1919.)

Figure 29.7 In-hospital clinical events among patients with and without heart failure (HF) or left ventricular systolic dysfunction (LVSD) ($P < 0.001$ for all events except reinfarction). Atrial fib, atrial fibrillation; V. tach/fib, ventricular tachycardia/ventricular fibrillation. (Redrawn from Velazquez EJ, Francis GS, Armstrong PW, et al: An international perspective on heart failure and left ventricular systolic dysfunction complicating myocardial infarction: The VALIANT Registry. *Eur Heart J* 2004;25:1911-1919.)

In patients with acute heart failure due to acute myocardial infarction, rapid reperfusion is the cornerstone of therapy and may be achieved with thrombolytic therapy, acute coronary angioplasty, or urgent coronary artery bypass surgery. In the GRACE Study, revascularization therapies were associated with a lower mortality rate in patients with ACS and acute heart failure.¹¹⁵

In patients who develop heart failure or significant left ventricular systolic dysfunction following myocardial infarction, a number of pharmacologic therapies have been shown in large placebo-controlled randomized studies to improve mortality rate and reduce repeat hospitalization. Beta blockers should be part of standard post-myocardial infarction therapy in these patients. In the CAPRICORN study, the use of carvedilol led to a significant 23% relative risk reduction.¹¹⁷ SAVE was the first trial to show that the use of an ACE inhibitor, captopril, was beneficial in post-myocardial infarction patients with ejection fractions below 40%.¹¹⁸ There was a 5% absolute mortality rate reduction after 42 months of follow-up. In AIRE, treatment with the ACE inhibitor ramipril, started 3 to 10 days after myocardial infarction in patients with heart failure, resulted in a significant mortality rate benefit at an average of 15 months of follow-up.¹¹⁹ Another trial showed that treatment with the ACE inhibitor trandolapril following myocardial infarction and an ejection fraction below 35% resulted in a significantly improved survival at 2 to 4 years of follow-up.¹²⁰ In VALIANT, a high dose of the ARB valsartan was as effective as an ACE inhibitor in improving survival and reducing cardiovascular morbidity.¹²¹

Therefore beta blockers and ACE inhibitors should be started early and continued long term in patients with reduced left ventricular ejection fraction following acute myocardial infarction. ARBs are recommended in those patients who are intolerant to ACE inhibitors.

Aldosterone blockers have also been shown to be effective in improving prognosis in patients with heart failure or left ventricular dysfunction following myocardial infarction and are recommended for these patients. The EPHEsus study

showed that eplerenone significantly reduced all-cause mortality rates and repeat hospitalizations at 16-month follow-up.¹²² Reduction in mortality rate and sudden cardiac death was noted as early as 30 days after initiation of eplerenone.¹²³

HEART FAILURE WITH PRESERVED LEFT VENTRICULAR EJECTION FRACTION (DIASTOLIC HEART FAILURE)

Heart failure can occur in patients with normal or relatively normal left ventricular systolic function. It is now recognized that in up to 50% of patients hospitalized with acute heart failure, the primary cardiac abnormality is diastolic dysfunction. There is no consistent definition or diagnostic test for diastolic heart failure. The European Society of Cardiology has proposed that this diagnosis can be applied to patients who present with clinical signs and symptoms of heart failure, who have normal left ventricular systolic function, and who have abnormal parameters of diastolic filling as demonstrated on Doppler echocardiography or invasive evaluation of diastolic function. A more practical definition includes the presence of heart failure and normal systolic function in the absence of primary valve disease.^{82,124}

Diastolic heart failure occurs due to impairment of left ventricular filling and abnormal left ventricular relaxation. Pathophysiology includes myocyte hypertrophy, increased amounts of collagen in extracellular matrix, increased wall stiffness and wall thickness, abnormal left ventricular geometry with increased left ventricular mass-to-volume ratio, fibrosis, and impaired compliance. There is impaired left ventricular filling at normal left atrial pressures, and thus an increase in left ventricular filling pressure is necessary to maintain cardiac output. This leads to chronic pulmonary venous hypertension and pulmonary congestion. Patients with diastolic heart failure usually demonstrate normal indices of left ventricular systolic performance and contractility.¹²⁵⁻¹²⁸

Diastolic heart failure is a common entity. The reported frequency of diastolic heart failure in the general heart failure population varies according to the definition of diastolic heart failure used. Some reports include patients with mildly abnormal systolic function (i.e., ejection fraction over 40%), whereas others restrict inclusion to patients with ejection fraction above 50%. Prevalence is also affected by the demographics of study populations, including age of patients, inpatient and outpatient status, the proportion of African Americans and women studied, and whether patients were evaluated at an academic referral center or a community-based setting.¹²⁴ In the general population of Olmsted County, Minnesota, moderate to severe diastolic dysfunction was seen in 7% of echocardiogram studies.² The prevalence of diastolic heart failure in population-based studies was 3.1% to 5.5% of patients over age 65.¹²⁴ The prevalence of diastolic heart failure may be increasing.¹²⁹ As compared with patients with systolic heart failure, patients with diastolic heart failure tend to be older, are more commonly women, and have a higher prevalence of hypertension and a lower incidence of coronary artery disease. In various studies, up to 50% of hospital admissions for heart failure in the United States are for patients with diastolic

heart failure. In an international observational database of 4953 hospitalizations for heart failure, 25% of patients had a left ventricular ejection fraction over 45%.¹³⁰ Up to 73% of patients with diastolic heart failure are women, with an incidence of hypertension or hypertensive heart disease of 64% to 78%. Reported incidences of concomitant diabetes (33-46%) and coronary artery disease (26-43%) are also high. Other common comorbid conditions include atrial fibrillation, abnormal renal function, and obesity.¹³¹⁻¹³⁴

Patients who present with heart failure due to diastolic dysfunction have a history and physical examination indistinguishable from patients with systolic heart failure. Presenting blood pressure may be higher, and acute “flash” pulmonary edema may be more common. Common exacerbating factors include severe hypertension, medication noncompliance, myocardial ischemia, and valve dysfunction. In one study, no precipitating factors could be identified in 50% of these patients.¹²⁹

The prognosis of patients with diastolic heart failure is serious. Mortality rate is probably not as high as in patients with systolic left ventricular dysfunction and heart failure, although one study found similar adjusted and nonadjusted mortality rates at 30 days and 1 year for hospitalized patients with heart failure and left ventricular ejection fraction less than 40% or greater than 50%.¹³⁵ In-hospital mortality rate is around 4%,¹⁰⁶ or four times age-matched control subjects.^{131,136} Annual mortality rate is variable and likely depends on the frequency of comorbid conditions in the cohort of patients studied; it has been reported in the range of 1.3% to 17.5%.¹²⁷ Readmission rates are as high as 50% at 1 year. Factors that identify patients with a worse prognosis include renal dysfunction, worse functional class, male gender, and advanced age.¹³⁶

Unlike systolic heart failure, there are no placebo-controlled randomized studies that have demonstrated effective therapy for diastolic heart failure. The CHARM-Preserved Study compared the use of the ARB candesartan with placebo in treating patients with heart failure and preserved systolic function. After an average 3-year follow-up, the mortality rate from cardiovascular cause or admission for heart failure was similar in the two groups. There was a modest impact on preventing hospitalizations due to heart failure in patients treated with candesartan.¹³⁷ The I-PRESERVE trial utilizing irbesartan in over 4000 patients with heart failure and left ventricular ejection fraction over 45% showed no beneficial effect on mortality rates or heart failure rehospitalizations.¹³⁸

Several basic recommendations are widely agreed upon. Effective treatment of underlying conditions, such as hypertension, diabetes mellitus, and coronary artery disease, is essential. Lowering systolic blood pressure will lower mean left atrial pressure. Control of elevated blood glucose may help to retard myocardial fibrosis by lessening cross-linking of myocardial collagen. Control of myocardial ischemia is important, although there are no convincing controlled data that revascularization will reliably prevent recurrences of diastolic heart failure. Maintenance of sinus rhythm and avoidance of tachycardia are also important. Medical therapy of diastolic heart failure is primarily focused on alleviating symptoms. Diuretics are effective at improving pulmonary congestion. Lower doses of diuretics are generally utilized, as high doses often lead to volume depletion

and hypotension in these patients with small left ventricular cavities. Long-acting nitrates are also useful to decrease left ventricular filling pressure, pulmonary venous pressure, and dyspnea.

Beta blockers can be useful to reduce heart rate and thus improve diastolic filling time. They are also effective medications for hypertension and coronary ischemia. Similarly, calcium channel blockers may improve symptoms of diastolic heart failure by treating hypertension and ischemia and improving diastolic relaxation. The use of ACE inhibitors and ARBs is helpful to lower blood pressure, reduce myocardial fibrosis, and block the adverse effects of the activation of the renin-angiotensin system. In a retrospective study of patients hospitalized with heart failure and ejection fraction greater than 40%, patients who were prescribed an ACE inhibitor had better quality of life scores, improved functional class, and lower adjusted mortality rate.¹³³ Aldosterone antagonists such as spironolactone or eplerenone treat hypertension and may reduce left ventricular hypertrophy and fibrosis.¹¹³ Therapy with positive inotropic drugs or digoxin are not useful in patients with diastolic heart failure.^{4,139,140} (Table 29.8).

ACUTE MYOCARDITIS AND HEART FAILURE

Myocarditis is defined as inflammation of heart muscle and is an uncommon cause of acute heart failure. Patients with acute myocarditis can develop severe left ventricular dysfunction and acute heart failure. In a minority of cases, myocarditis can present with fulminant heart failure and cardiogenic shock, with a high mortality rate.^{141,142} A large body of experimental animal data indicates that viral myocarditis results in activation of immune mechanisms, which can also result in chronic dilated cardiomyopathy and chronic heart failure.¹⁴¹

An infectious cause of myocarditis is common. Viral agents such as enterovirus and adenovirus have been implicated as causative agents by serologic data and examination of cardiac cell genomes. The protozoan *Trypanosoma cruzi* is the etiologic agent in Chagas' disease, a form of myocarditis that can lead to chronic heart failure, endemic in Central and South America. Immune mechanisms are pathogenic in the myocarditis due to giant cell arteritis and the myocarditis associated with progressive systemic sclerosis, systemic lupus erythematosus, and polymyositis.

Myocarditis is a diagnosis made on clinical grounds and should be suspected in patients who present with new-onset heart failure, with or without antecedent flu-like symptoms. Chest pain may be present. Elevated leukocyte count, elevated erythrocyte sedimentation rate, elevated creatinine kinase and troponin levels, and ECG changes suggestive of myocardial ischemia or infarction may be seen but are not always present. Endomyocardial biopsy may be used to aid in the diagnosis of myocarditis. However, histologic findings of both inflammation and myocyte necrosis in biopsy specimens have been very insensitive in making the diagnosis and have a high degree of interobserver variability. In patients suspected of having myocarditis on clinical grounds, only 10% to 67% of patients have had positive biopsies in reported series.^{141,142} Cardiac magnetic resonance imaging

Table 29.8 Recommendations for Treatment of Patients with Heart Failure and Normal Left Ventricular Ejection Fraction

Recommendation	Class*	Level of Evidence†
Physicians should control systolic and diastolic hypertension in accordance with published guidelines.	I	A
Physicians should control ventricular rate in patients with atrial fibrillation.	I	C
Physicians should use diuretics to control pulmonary congestion and peripheral edema.	I	C
Coronary revascularization is reasonable in patients with coronary artery disease in whom symptomatic or demonstrable myocardial ischemia is judged to be having an adverse effect on cardiac function.	IIa	C
Restoration and maintenance of sinus rhythm in patients with atrial fibrillation might be useful to improve symptoms.	IIb	C
The use of β -adrenergic blocking agents, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, or calcium antagonists in patients with controlled hypertension might be effective to minimize symptoms of heart failure.	IIb	C
The use of digitalis to minimize symptoms of heart failure is not well established.	IIb	C

*I: There is evidence or general agreement that therapy is beneficial, useful, and effective; IIa: there is conflicting evidence about the usefulness of therapy, but the weight of the evidence is in favor of efficacy; IIb: there is conflicting evidence about the usefulness of therapy, and use is less well established by evidence/opinion.

†A: Data are derived from multiple randomized clinical trials or meta-analysis; C: only consensus opinion of experts, case studies, or standard of care.

Adapted from Hunt S, Abraham WT, Chin M, et al: ACC/AHA 2005 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult—Summary Article. A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society of Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation* 2005;112:1825-1852.

has more recently been shown to be an important tool in the diagnosis of myocarditis.^{143,144}

Pharmacologic management of heart failure due to myocarditis is similar to the management of heart failure from other causes. Diuretics, ACE inhibitors, and beta blockers should be prescribed. Many patients will experience significant spontaneous improvement in left ventricular function during the first 6 months after diagnosis. The use of corticosteroids and other immunosuppressive drugs is controversial. Early studies suggested a small improvement in left ventricular ejection fraction with the use of corticosteroids.¹⁴⁵ Other studies suggest targeting immunosuppressive drugs to patients with signs of immune activation.¹⁴⁶ The Myocarditis Treatment Trial showed no significant benefit with immunosuppressive therapy, although there are several procedural problems with this study.¹⁴⁷ We generally recommend a 1- to 3-month trial of corticosteroids and azathioprine in patients with myocarditis and left ventricular dysfunction who are not improving spontaneously after 1 to 2 months with conventional heart failure therapies or who continue to worsen acutely. If the immunosuppressive regimen produces an improvement in ejection fraction, it can then be tapered over a 6- to 12-month period.¹⁴²

Myocarditis with acute, severe heart failure and cardiogenic shock is termed fulminant myocarditis. These patients often require treatment with intravenous vasodilators and inotropes and may be candidates for implantation of a VAD as a bridge to recovery or transplantation. When supported aggressively, most patients will recover fully with normal ventricular function, and fulminant myocarditis has a good late prognosis. Therefore, aggressive supportive therapy,

including the use of VADs, is indicated, even in gravely ill patients.¹⁴⁸ Cardiac transplantation may be necessary for patients who do not improve.

DEVICE THERAPY: IMPLANTED CARDIOVERTER-DEFIBRILLATORS AND CARDIAC RESYNCHRONIZATION THERAPY

Sudden death is a frequent occurrence in heart failure patients, especially in patients with cardiomyopathy due to coronary artery disease. Sudden death is presumed to be due to sustained ventricular arrhythmia in the majority of cases. It is estimated that 30% of patients with heart failure and ejection fractions under 30% die suddenly. The implanted cardioverter-defibrillator (ICD) is standard therapy and is indicated for both secondary prevention of life-threatening ventricular arrhythmias as well as primary prevention of sudden cardiac death in patients with severe left ventricular systolic dysfunction. This therapy is supported by the results of several large, randomized controlled trials.

Prophylactic antiarrhythmic drug therapy aimed at preventing sudden arrhythmic cardiac death has been shown to be ineffective and may even worsen prognosis. In the Cardiac Arrhythmia Suppression Trial (CAST), patients with coronary artery disease, a history of myocardial infarction, and frequent premature ventricular contractions on baseline Holter monitoring had an increased mortality rate when treated with the antiarrhythmic drugs encainide or

flecainide, despite good suppression in frequency of arrhythmia on follow-up Holter monitoring.¹⁴⁹ This adverse effect on mortality rate is presumed due to the known potential for these drugs to worsen arrhythmia (“proarrhythmia”). Therefore, class IA and IC antiarrhythmic drugs quinidine, procainamide, disopyramide, flecainide, and propafenone are not useful for prevention of sudden death and are contraindicated in patients with heart failure and left ventricular systolic dysfunction.

Amiodarone was also studied for primary prevention of sudden death, as the propensity for proarrhythmia is less than with type I antiarrhythmics; 675 patients with heart failure and ejection fractions below 40% were randomized to treatment with amiodarone or placebo, with no survival difference between the two groups at 45 months.¹⁵⁰ There was a trend toward reducing mortality rates with amiodarone in patients with nonischemic cardiomyopathy. In another study, 1486 post-myocardial infarction patients with ejection fractions under 40% were randomized to amiodarone or placebo with no difference in mortality rates in 21 months, although there was a suggestion of a reduction in deaths due to arrhythmia.¹⁵¹ Unlike the findings in CAST, there was no observed increased risk of death with amiodarone. Thus, this medication is not helpful in the prevention of sudden cardiac death, but it is considered safe for treatment of supraventricular arrhythmias in heart failure patients.

IMPLANTED CARDIOVERTER-DEFIBRILLATOR THERAPY

The ICD was compared to antiarrhythmic drugs for secondary prevention of sudden cardiac death in the AVID study. These patients had been resuscitated from cardiac arrest or survived ventricular tachycardia associated with syncope and had ejection fractions under 40%. In the study 1016 patients were randomized to receive an ICD or antiarrhythmic drugs (over 90% received amiodarone). There was a statistically improved survival rate with ICD therapy at 1, 2, and 3 years of follow-up.¹⁵² In two other studies of similar patients, a nonsignificant reduction in rates of all-cause mortality and arrhythmic death was seen with the ICD when compared to amiodarone,^{153,154} and increased mortality rate was seen with propafenone therapy (a class IC antiarrhythmic).¹⁵⁴ Published guidelines recommend ICDs as first-line therapy, in preference to antiarrhythmic drugs, in patients with ischemic and nonischemic cardiomyopathy who have survived a cardiac arrest or an episode of sustained ventricular tachycardia.⁸²

ICD therapy has also been evaluated as primary prevention of arrhythmic death in patients with coronary heart disease and previous myocardial infarction with left ventricular dysfunction, without symptomatic clinical arrhythmias, and also in patients with nonischemic cardiomyopathy. In MADIT I, post-myocardial infarction patients with ejection fractions below 35% and asymptomatic nonsustained ventricular tachycardia on monitoring were studied with electrophysiologic testing. Patients were enrolled in this study if they had inducible ventricular tachycardia not suppressed with antiarrhythmic therapy. At 2 years of follow-up, total mortality rate was significantly reduced from 39% in the medically treated group (standard medical therapy with

or without amiodarone) to 15% in the ICD group.¹⁵⁵ In the MUSTT study, a similar cohort of patients showed an improvement in mortality rate from 55% in patients treated with medication to 24% in patients treated with ICDs at 5 years.¹⁵⁶ In MADIT II, the patient population was extended to include patients with a history of myocardial infarction and ejection fractions of less than 30%. Importantly, in this study, neither ventricular arrhythmias seen on monitoring nor those induced at electrophysiologic study were necessary for inclusion. A statistically significant improvement in total mortality rate was seen in patients treated with ICDs, from 19.8% to 14.2% at 4 years¹⁵⁷. It should be noted that class IV heart failure patients were not included in any of these studies.

The Sudden Cardiac Death Heart Failure Trial (SCD-HeFT) enrolled patients with functional class II and III heart failure with left ventricular ejection fractions under 35%. This study differed from MADIT I and II in that a greater number of patients (48%) had nonischemic cardiomyopathy. Primary prevention of sudden cardiac death was compared among standard heart failure pharmacologic therapy, standard therapy combined with amiodarone, and standard therapy plus an ICD. After a mean follow-up of 45.5 months, mortality rate was improved from 29% in the medical group and 28% in the amiodarone group to 22% in the ICD group, which was statistically significant. This improvement was particularly notable in class II heart failure patients.¹⁵⁸ Benefits of ICD therapy were seen in patients with both ischemic and nonischemic cardiomyopathy. In the DEFINITE study, the use of the ICD as primary prevention was evaluated in 458 patients with nonischemic cardiomyopathy who had ventricular arrhythmia seen on routine monitoring. After a mean follow-up of 29 months, total mortality rate was not significantly reduced (17.5% with placebo vs. 12% in ICD, $P = 0.08$) but prevention of sudden death was significantly reduced.¹⁵⁹ A meta-analysis of all studies in which ICDs were used as primary prevention in patients with nonischemic cardiomyopathy indicated a statistically significant 31% relative risk reduction in favor of ICDs.¹⁶⁰

Thus, the approved use of ICD therapy for prevention of sudden cardiac death has been extended to prophylactic primary prevention therapy in patients with symptomatic heart failure, class II-III and left ventricular ejection fractions under 35% due to both ischemic as well as nonischemic cardiomyopathy.⁸²

CARDIAC RESYNCHRONIZATION THERAPY

In many patients with heart failure, there is abnormal timing and coordination of systolic motion of the intraventricular septum and left ventricular free wall, termed dyssynchrony. This often coexists with His-Purkinje conduction system disease, with marked QRS prolongation on ECG.¹⁶¹ In fact, left bundle branch block pattern with long QRS duration is associated with an increase in all-cause mortality rate in heart failure patients. Pacemaker therapies have been developed to correct left ventricular dyssynchrony, delivering timed pacing to both intraventricular septum and left ventricular free wall. This is termed biventricular pacing or cardiac resynchronization therapy (CRT). Standard dual-chamber transvenous leads are placed in the right atrium

(in the absence of chronic atrial fibrillation) and right ventricle. The left ventricular free wall is paced via a third electrode passed through the coronary sinus into an epicardial lateral cardiac vein. Alternatively, a left ventricular lead can be placed directly on the epicardium of the lateral wall of the left ventricle via thoracoscopy. The pacemaker is programmed to coordinate timing of septal stimulation via the right ventricle with left ventricular lateral wall stimulation^{161,162} (Fig. 29.8).

In the MIRACLE trial, 453 patients with ejection fractions under 35% and class III-IV heart failure and QRS duration greater than 130 ms were treated with standard medical therapy or resynchronization therapy plus medical therapy. At 6 months of follow-up, CRT resulted in a statistically significant improvement in 6-minute walking distance, quality of life score, and functional class, with fewer hospitalizations for recurrent heart failure.¹⁶¹ No significant mortality rate improvement was noted during a relatively short follow-up period. There was an 8% rate of unsuccessful left ventricular lead placement and a 1.2% incidence of serious complications of implantation of the pacemaker device, including coronary sinus dissection or perforation. A meta-analysis of three major resynchronization trials in 1634 patients concluded that chronic resynchronization therapy was associated with a statistically significant 51% reduction in death from progressive heart failure.¹⁶³

In the CARE-HF study, resynchronization therapy (without ICD) was evaluated in 813 patients with class III-IV heart failure due to left ventricular systolic dysfunction, with ejection fraction under 35% and QRS duration greater than 150 ms or QRS duration greater than 120 ms with signs of dyssynchrony on echocardiography. The primary end point of all-cause mortality rate plus unplanned hospitalization from cardiovascular causes was reduced from 55% in medically treated patients to 39% in resynchronization patients ($P < 0.001$). All-cause mortality rate was reduced from 30% to 20% with resynchronization therapy ($P < 0.002$). Mean follow-up was 29.4 months. Measures of quality of life were

improved, and ejection fractions improved.¹⁶⁴ Thus, resynchronization therapy alone, without an ICD, can reduce mortality rates as well as improve symptoms in chronic heart failure patients.

Devices combining biventricular pacing and ICD capabilities were evaluated in patients with systolic heart failure and low ejection fraction. These patients often have indications for both devices. The rationale is to decrease morbidity and mortality rates associated with progressive heart failure as well as decrease mortality rates associated with sudden life-threatening ventricular arrhythmia. Biventricular pacing does not interfere with appropriate ICD detection and termination of ventricular arrhythmias.¹⁶⁵ The COMPANION trial enrolled 1520 patients with advanced heart failure, functional class III-IV, in sinus rhythm, who had the ECG finding of QRS duration greater than 120 ms. Therapies compared were best pharmacologic heart failure therapy, best therapy along with biventricular pacing, and best therapy along with combination biventricular pacing and ICD. Successful implantation occurred in 87% to 91% of patients in the latter two groups, with a procedural mortality rate of 0.5% to 0.8%. The primary end points of death from any cause or hospitalization for any cause, followed over 12 months, were 68% in the drug therapy group and 56% in both device groups, a significant difference. One-year rates of death or hospitalization due to cardiovascular cause were 60% in the drug group, with a relative risk reduction of 25% in the biventricular pacing group and 28% in the biventricular pacing/ICD group. The authors concluded that there was a significant reduction in heart failure hospitalizations with biventricular pacing, and there was an additional significant reduction in mortality rate when ICD therapy was added. Improvement occurred in both patients with ischemic and those with nonischemic cardiomyopathy.¹⁶⁶

CRT was then studied in class II and III heart failure patients with ejection fraction below 30%; 1798 patients with QRS duration greater than 120 ms during native conduction, or 200 ms during ventricular pacing, were treated

Figure 29.8 A, Placement of pacing wires in biventricular pacing. B, Lack of coronary sinus venous branch necessitates epicardial placement of third lead via minimally invasive surgical procedure.

with an ICD alone or with ICD plus CRT. At a mean follow-up of 40 months, there was a significant improvement with CRT in the primary end point of all-cause mortality rate plus hospitalization for heart failure (33.2% with CRT-ICD versus 40.3% with CRT alone, $P < 0.001$). Therefore, CRT has been successfully extended to class II heart failure patients with low ejection fraction.¹⁶⁷

Currently, devices combining CRT with ICD are recommended for patients with left ventricular systolic dysfunction with ejection fraction under 35%, QRS duration 120 ms or greater on ECG, in sinus rhythm, and class II-IV heart failure symptoms despite optimal medical therapy. These devices provide both symptomatic benefit and improve survival in patients with heart failure.

MECHANICALLY ASSISTED CIRCULATORY SUPPORT: VENTRICULAR ASSIST DEVICES

It is estimated that over 100,000 patients in the United States have advanced functional class IV heart failure. These patients have a very poor short-term prognosis, even with appropriate pharmacologic and device therapy.¹⁶⁸ Cardiac transplantation offers an effective therapy for many patients with end-stage heart failure and is currently associated with a 1-year survival rate of over 80%. However, the pool of donor hearts is currently less than 3000 per year in the United States, and it is not increasing.^{169,170} There is a role for mechanically assisted circulatory support in these patients utilizing VADs, which support or replace the function of the failing heart. VADs provide normal cardiac output and flow to vital organs.

Patients with heart failure who may benefit from VAD therapy are those with the worst prognosis, such as patients with refractory cardiogenic shock. In patients with chronic heart failure, factors that indicate a very poor prognosis include inability to wean from parenteral inotropic drugs, persistent class IV symptoms despite optimal medical and device therapy, progressive cardiorenal dysfunction precluding the use of ACE inhibitors, and hypotension preventing the use of ACE inhibitors or beta blockers.¹⁶⁸ Peak oxygen consumption of less than 12 mL/kg/minute on cardiopulmonary stress testing is also a poor prognostic indicator. Specific acute clinical circumstances in which VADs can be considered include cardiogenic shock following acute myocardial infarction or cardiac surgery, fulminant myocarditis, or severe postpartum cardiomyopathy.¹⁷¹ A classification system to define the severity of heart failure illness and the urgency of the need for mechanically assisted circulatory support has been adopted (Fig. 29.9).

There are five clinical scenarios for the use of mechanical circulatory assistance:

1. VADs can be used as a bridge to cardiac transplantation. A mortality rate of 30% has been reported in patients listed for and awaiting heart transplantation, so VADs may enable many patients to survive to obtain transplantation.
2. VADs can be used as a “bridge to decision.” These patients have urgent need for support but have severe medical conditions exacerbated by heart failure that make transplantation an initial poor option. These medical

conditions may improve after a period of improved circulation with a VAD so that transplantation may become feasible.

3. VADs may be used as a bridge to definitive surgical therapy, such as in patients with severe ischemic heart disease who require coronary revascularization, which may lead to recovery of myocardial function.
4. A small minority of patients may require VAD therapy as a bridge to recovery, when improvement in cardiac function with nonsurgical approaches is expected. An example of this is patients with acute fulminant myocarditis.¹⁴⁸ In addition, there have been case reports of patients with subacute cardiomyopathy and severe heart failure who received VAD support for months and had improvement in left ventricular function such that the VAD was removed and patients survived without cardiac transplantation.¹⁷² However, only 5% to 10% of patients with chronic heart disease will improve sufficiently for VAD removal.
5. Finally, current VADs have a low incidence of pump failure and can be used as long-term support, or “destination therapy.”

Catheter-based pumps can be used for acute hemodynamic support and can provide cardiac output up to 3.5 L/minute.¹⁷¹ These systems are implanted percutaneously and provide circulatory support for several days. The Tandem-Heart device (CardiacAssist, Pittsburgh, PA) requires placement of a catheter via a transatrial septal puncture. The Impella pump (Abiomed, Danvers, MA) is entirely intracorporeal and pulls blood from the left ventricle and pumps through the catheter tip in the aorta at a flow of 2.5 L/minute.¹⁷³

The first VADs to be used were large extracorporeal devices, inserted via a midline sternotomy, that provided pulsatile flow. Because there were many moving parts, there was a high incidence of pump failure. Current VADs are smaller, are placed intracorporeally, and provide continuous, nonpulsatile flow. These have significantly improved long-term durability and are suitable for long-term support. Battery packs are small and wearable, so patients with VADs have freedom of movement and can participate in rehabilitation and normal daily activities (see Fig. 29.10). These devices do require systemic anticoagulation and antiplatelet therapy. A study comparing continuous flow VADs with pulsatile flow devices was reported in 2009; 200 patients were studied who had advanced heart failure and were ineligible for cardiac transplantation. The continuous flow device was associated with improved 2-year survival, fewer adverse events, fewer rehospitalizations, and improved quality of life. The incidence of pump failure requiring VAD replacement was reduced by 87%.¹⁷⁴ The Heart Mate II continuous flow VAD was approved for use in 2008 and was approved to be used as destination therapy in 2010.

A very important issue in VAD therapy is appropriate patient selection. Hemodynamic indications for use include persistent hypotension with systolic blood pressure less than 80 mm Hg, PCWP greater than 20 mm Hg, and cardiac index less than 2 L/minute/m² despite maximal pharmacologic support. Patient characteristics that define a worse prognosis with VAD therapy include older age, malnourishment (low albumin), renal dysfunction (i.e., serum

INTERMACS profile descriptions	Time frame for intervention
<p>Profile 1: Critical Cardiogenic shock Patient with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. <i>"Crash and burn"</i>.</p>	Definitive intervention needed within hours.
<p>Profile 2: Progressive decline Patient with declining function despite intravenous inotropic support, may be manifest by worsening renal function, nutritional depletion, inability to restore volume balance <i>"Siding on inotropes"</i>. Also describes declining status in patients unable to tolerate inotropic therapy.</p>	Definitive intervention needed within few days.
<p>Profile 3: Stable but inotrope dependent Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both), but demonstrating repeated failure to wean from support due to recurrent symptomatic hypotension or renal dysfunction <i>"Dependent stability"</i>.</p>	Definitive intervention elective over a period of weeks to few months.
<p>Profile 4: Resting symptoms Patient can be stabilized close to normal volume status but experiences daily symptoms of congestion at rest or during ADL. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuttle between 4 and 5.</p>	Definitive intervention elective over period of weeks to few months.
<p>Profile 5: Exertion intolerant Comfortable at rest and with ADL but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk than INTERMACS 4 and require definitive intervention.</p>	Variable urgency, depends upon maintenance of nutrition, organ function, and activity.
<p>Profile 6: Exertion limited Patient without evidence of fluid overload is comfortable at rest and with activities of daily living and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. <i>"Walking wounded"</i>.</p>	Variable, depends upon maintenance of nutrition, organ function, and activity level.
<p>Profile 7: Advanced NYHA II A placeholder for more precise specification in future, this level includes patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.</p>	Transplantation or circulatory support may not currently be indicated.
<p>Modifiers for Profiles TCS-Temporary Circulatory Support – can modify only patients in hospital (other devices would be INTERMACS devices) includes IABP, ECMO, TandemHeart, Levitronix, BVS 5000 or AB5000, Impella.</p>	Possible Profiles to Modify 1,2,3 in hospital.
<p>A-Arrhythmia – can modify any profile. Recurrent ventricular tachyarrhythmias that have recently contributed substantially to clinical compromise. This includes frequent ICD shock or requirement for external defibrillator, usually more than twice weekly.</p>	Any profile.
<p>FF-Frequent Flyer – can modify only outpatients, designating a patient requiring frequent emergency visits or hospitalizations for diuretics, ultrafiltration, or temporary intravenous vasoactive therapy.</p>	3 if at home, 4,5,6. A frequent flyer would rarely be profile 7.

Figure 29.9 A classification of heart failure syndromes, with level 1 representing the most critical illness with an urgent need for mechanically assisted circulatory support. Levels 1 through 5 include patients with New York Heart Association (NYHA) class IV heart failure. Levels 5 and 6 describe patients with advanced NYHA class III heart failure. (From Stevenson LW, Pagani FD, Young JB, et al: INTERMACS profiles of advanced heart failure: The current picture. J Heart Lung Transplant 2009;28:535-541.)

Figure 29.10 A continuous flow left ventricular assist device. The axial, continuous flow device is implanted within the chest and is attached to an external power source. (From Pagani FD, Miller LW, Russell SD, et al: Extended mechanical circulatory support with a continuous-flow rotary left ventricular assist device. *J Am Coll Cardiol* 2009;54:312-321.)

creatinine >3.0 mg/dL or BUN >51 mg/dL), hepatic dysfunction (elevated transaminase, bilirubin, and international normalized ratio), coagulopathy, neurologic deficits, low mean pulmonary artery pressure (reflecting right ventricular dysfunction), and anemia.^{168,175} Contraindications to the use of VADs include severe chronic obstructive pulmonary disease, need for hemodialysis, aortic insufficiency, or aortic valve mechanical prosthesis.¹⁶⁸ Risk scores have been developed to attempt to define appropriate patient selection but need prospective validation. The major complications of VAD therapy include right ventricular failure, sepsis, thromboembolic complications including stroke, and bleeding often associated with an acquired von Willebrand factor deficiency. In patients who were deemed at lower risk, there was a 93.7% survival rate to hospital discharge and 81.2% 1-year survival rate. The highest risk patients had only 13.7% hospital survival rate and 10.7% 1-year survival rate.¹⁷⁵

VADs are more frequently being used as long-term or “destination therapy.” The REMATCH trial compared the pulsatile flow VAD as destination therapy with standard optimal heart failure medical therapy in 129 patients with class IV heart failure, ejection fraction less than 25%, and initial dependence on intravenous inotropes. This study showed improved survival and quality of life in patients treated with first-generation VADs. Survival rate at 1 year was 52% with a VAD as compared with 25% with medical therapy, but 2-year survival rate with VAD support was only 23% (compared with 8% for medical therapy).¹⁷⁶ The prognosis

with current VAD technology is significantly better. In 2011, there were approximately 1500 VAD implants in the United States, virtually all of which were continuous flow devices: 23.7% were used as a bridge to transplant, 40.5% were used to determine transplant candidacy, and 34% were implanted as destination therapy. A classification system can be used to define short-term prognosis and suitability for VAD implantation¹⁷⁷ (see Fig. 29.9). Of patients receiving VADs, 14% had critical cardiogenic shock at the time of implant, 41.4% were failing continuous intravenous inotrope therapy, 27.7% were stable on inotrope therapy, and 12.1% had severe class IV symptoms at rest but were out of hospital. Current actuarial 1-year survival rate in all VAD recipients is 80%, with 2-year survival rate of 70%.¹⁷⁸

With refinements in design and technologic improvements, long-term mechanical support of the failing left ventricle is now feasible for indefinite periods of time, especially as the incidence of infectious and thromboembolic complications are reduced. Newer VAD designs will incorporate totally implanted systems without external drive lines, which will significantly reduce the incidence of infectious complications.

KEY POINTS

- The diagnosis of heart failure is based on clinical findings and is supported by laboratory evidence, including serum natriuretic peptide levels and imaging with chest radiography and echocardiography.
- Factors that identify heart failure patients with a poorer prognosis include elevated BUN and creatinine, low systolic blood pressure, hyponatremia, markedly elevated BNP, and elevated serum troponin.
- When patients with chronic heart failure are admitted to hospital with acute decompensation, it is important to determine the reason for the acute change in status in order to attempt to reduce the risk of future episodes of decompensation and rehospitalization.
- The natural history of chronic heart failure with left ventricular systolic dysfunction involves progressive worsening of cardiac function and heart failure, which can be stabilized or improved with appropriate pharmacologic therapy, which includes beta blockers, angiotensin-converting enzyme inhibitors (or angiotensin receptor blockers), and aldosterone antagonists.
- Therapy with intravenous inotropes should be used only when heart failure is complicated by signs of systemic end-organ hypoperfusion or cardiogenic shock.
- Acute ischemia due to coronary artery disease should always be considered as a potential etiologic factor in patients presenting with acute heart failure. When ischemia is identified, aggressive revascularization therapies should be strongly considered to improve prognosis.
- Primary diastolic LV dysfunction, with normal LV systolic function, is a common cause of acute heart

KEY POINTS (Continued)

failure and is more often seen in elderly patients, hypertensive patients, and women.

- Devices that combine cardiac resynchronization (“biventricular pacing”) with an internal cardioverter-defibrillator improve heart failure symptoms and improve survival in heart failure patients with low LV ejection fraction and prolonged QRS complex on ECG.
- As technology and design continue to improve, fully implanted mechanical ventricular assist devices will be used more often to support critically ill patients and will be used as long-term therapy to support patients with the most severe and refractory heart failure.

DEFINITIONS

Acute coronary syndrome (ACS) refers to “any constellation of clinical symptoms that are compatible with acute myocardial ischemia.”¹ Therefore, the ACS spectrum encompasses unstable angina (UA), non-ST segment elevation myocardial infarction (NSTEMI), and ST segment elevation myocardial infarction (STEMI). The presence or absence in the blood of either troponin or the MB fraction of creatine kinase (CK-MB) determines the distinction between a diagnosis of either UA or myocardial infarction (MI). (For convenience, these and other relevant abbreviations are listed in [Table 30.1](#).) An expert consensus document titled the “Third Universal Definition of Myocardial Infarction” was published in 2012 by a joint task force of the European Society of Cardiology, the American College of Cardiology Foundation (ACCF), the American Heart Association (AHA), and the World Heart Federation.² The clinical diagnosis of an acute MI was defined as a rise or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia with at least one of the following: symptoms of ischemia, ECG changes indicative of new ischemia (new ST-T changes or new left bundle branch block), development of pathologic Q waves in the electrocardiogram (ECG), or imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.² Definitions also exist for the diagnosis of an acute MI in three other circumstances: sudden death, after percutaneous coronary intervention (PCI), and after coronary artery bypass graft (CABG) surgery.²

The increased sensitivity of troponin compared with CK-MB and the new criteria for the diagnosis of acute MI

dictate that many patients who were classified as having UA by the old criteria are now given a diagnosis of acute MI. Among 1851 patients who were enrolled in a prospective study, 538 patients received a diagnosis of acute MI based on dynamic changes in troponin T, compared with only 427 patients when CK-MB was used to diagnose acute MI, representing a 41% increase.³ A retrospective analysis of 2181 patients with suspected ACS and no ST segment elevation found that the prevalence of acute MI ranged from 9.7% to 22% based on differing troponin-based definitions, compared with 7.8% based on CK-MB alone.⁴ Meier and colleagues⁵ studied 493 consecutive patients with suspected ACS. Of those, 224 patients had elevated CK-MB, and an additional 51 patients had normal CK-MB but elevated troponin I. The latter group was characterized by a greater incidence of comorbid conditions and higher 6-month mortality. Among 29,357 patients with non-ST segment elevation ACS who were enrolled in a registry called “Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes with Early Implementation of the ACC/AHA Guidelines?” (CRUSADE), 18% of patients were CK-MB negative and troponin positive.⁶ The risk of in-hospital death was significantly increased among troponin-positive patients regardless of CK-MB status.

The Global Registry of Acute Coronary Events (GRACE) is a prospective observational registry of 26,267 patients with ACS who were admitted to 106 hospitals in 14 countries.⁷ (A list of eponyms in use for various cardiac registries and drug trials is provided in [Table 30.2](#).) Among the 10,719 patients (10.4%) with both CK-MB and troponin data, 1110 patients without elevation of CK-MB were diagnosed with acute MI by virtue of elevated troponin. Patients who were troponin negative had similar 6-month mortality regardless

Table 30.1 Cardiac Critical Care Abbreviations

ACC	American College of Cardiology
ACCF	American College of Cardiology Foundation
ACE	angiotensin-converting enzyme
ACS	acute coronary syndrome
ACT	activated clotting time
AF	atrial fibrillation
AHA	American Heart Association
APSAC	anisoolated plasminogen-streptokinase activator complex
aPTT	activated partial thromboplastin time
ARB	angiotensin receptor blocker
AVB	atrioventricular block
BMS	bare metal stent
BNP	brain natriuretic peptide
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CHF	congestive heart failure
CI	confidence interval
CK-MB	MB* fraction of creatine kinase
CT	computed tomography
DES	drug-eluting stent
ECG	electrocardiogram
EF	ejection fraction
ESC	European Society of Cardiology
GP	glycoprotein
HDL	high-density lipoprotein
IABP	intra-aortic balloon pump
ICH	intracranial hemorrhage
ICU	intensive care unit
ICD	implantable cardioverter-defibrillator
INR	international normalized ratio
IRA	infarct-related artery
LAD	left anterior descending (artery)
LBBB	left bundle branch block
LDL	low-density lipoprotein
LMWH	low-molecular-weight heparin
LVEF	left ventricular ejection fraction
MI	myocardial infarction
MR	mitral regurgitation
MRI	magnetic resonance imaging
NNT	number needed to treat
NO	nitric oxide
NSAIDs	nonsteroidal anti-inflammatory drugs
NSTEMI	non-ST segment elevation myocardial infarction
NTG	nitroglycerin
PA	pulmonary artery
PCI	percutaneous coronary intervention
PCWP	pulmonary capillary wedge pressure
RCA	right coronary artery
rPA	reteplase
RVMI	right ventricular myocardial infarction
SK	streptokinase
STEMI	ST segment elevation myocardial infarction
tPA	tissue plasminogen activator
UA	unstable angina
UFH	unfractionated heparin
VF	ventricular fibrillation
VSR	ventricular septal rupture
VT	ventricular tachycardia

*Muscle-brain.

of CK-MB status, but patients who were CK-MB negative and troponin positive had a twofold greater hospital case-fatality rate.

The advent of highly sensitive troponin assays has contributed to further changes in the detection of acute MI in patients with myocardial ischemia.⁸⁻¹⁰ Bonaca and colleagues⁸ conducted a prospective study of the prognostic value of a sensitive assay for cardiac troponin I in 4513 patients with non-ST segment elevation ACS who were enrolled in a randomized trial of ranolazine versus placebo. Patients with low-level increases of serum troponin I (0.04 mcg/L to < 0.1 mcg/L) had a significantly higher risk of death at 12 months (6.4% versus 2.4%, $p = 0.005$). Another study found that implementation of a sensitive assay for troponin I in patients with suspected ACS increased the detection of MI by 29%, identified patients who were at the highest risk of recurrent MI and death, and was associated with improved clinical management that resulted in fewer deaths and admissions with recurrent MI.⁹

ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

CLINICAL MANIFESTATIONS

CLINICAL HISTORY

The initial differentiation of ACS from other causes of chest pain is based on the chest pain history, physical examination, presence of risk factors for CAD, and the ECG. Certain chest pain characteristics are associated with decreased or increased likelihoods of ACS.¹¹ The feature that was found to be associated with the highest risk of a diagnosis of ACS is radiation of pain to one or both shoulders or arms. A prospective study of patients who presented to an emergency department for evaluation of chest pain determined that pain relief by nitroglycerin is not a useful indicator of the presence or absence of ACS.¹² Nitroglycerin relieved chest pain in 35% of patients with active CAD, compared with 41% of patients without active CAD ($p > 0.2$).¹²

Another literature review included 15 studies published from 1989 to 2002 that identified symptoms of ACS.¹³ Chest pain was the most common symptom among both men and women, but atypical symptoms were common, especially among women. Compared with men, women with ACS were significantly more likely to report back and jaw pain, nausea, vomiting, dyspnea, indigestion, and palpitations. A significant fraction of patients with acute MI do not complain of chest pain at the time of presentation.¹⁴⁻¹⁶ A total of 1674 U.S. hospitals contributed patients to the National Registry of Myocardial Infarction (NRMI) 2.¹⁴ Among 434,877 patients with confirmed MI who were enrolled in the NRMI-2 registry between June 1994 and March 1998, 142,445 (33%) did not have chest pain at the time of presentation to the hospital. There were several notable differences between the groups who presented with and without chest pain. Only 23% of patients without chest pain had ST segment elevation on the initial ECG, compared with 47% of the patients with chest pain. The group of patients who presented without chest pain was older (74 versus 67 years) and had a higher proportion of women (49% versus 38%). A subsequent analysis of 1,143,513 patients who were enrolled in

Figure 30.1 In-hospital mortality rate in subgroups with acute coronary syndrome (ACS) according to presenting symptoms. Ant, anterior; Inf/lat, inferior or lateral; NSTEMI, non-ST segment elevation myocardial infarction; STEMI, ST segment elevation myocardial infarction. (From Brieger D, Eagle KA, Goodman SG, et al: Acute coronary syndromes without chest pain, an underdiagnosed and undertreated high-risk group: Insights from the Global Registry of Acute Coronary Events. *Chest* 2004;126:461-469.)

the registry found that the proportion of patients who presented without chest pain was significantly higher for women than men (42% versus 30.7%; $p < 0.001$).¹⁶ The gender differences in clinical presentation without chest pain diminished with increasing age.¹⁶

The absence of chest pain has a major impact on hospital management and outcomes, even among patients who present with ST segment elevation.¹⁴⁻¹⁶ A report from the GRACE registry compared 6385 patients with STEMI and typical symptoms with 541 patients whose presenting symptoms did not include chest pain.¹⁵ Patients without chest pain were significantly less likely to receive reperfusion therapy (i.e., fibrinolysis or primary PCI, β -blockers), and aspirin. Perhaps as a consequence of undertreatment, hospital mortality was significantly greater among patients with STEMI and no chest pain than among patients with chest pain (18.7% versus 6.3%; $p > 0.001$) (Fig. 30.1).

There is a longstanding belief that diabetes is associated with silent myocardial ischemia and painless MI due to autonomic neuropathy. Nevertheless, in the NRM1 2 registry, only 33% of the patients with painless MI had diabetes mellitus, and in the GRACE registry, only 32% of patients with painless ACS had diabetes.^{14,15}

PHYSICAL EXAMINATION

The initial physical examination provides important prognostic information in patients with acute MI. Killip and Kimball published their classic study in 1967.¹⁷ Among 250 patients with acute MI, 81 patients (33%) had no heart failure (Killip class I), 96 (38%) had mild heart failure (Killip class II), 26 (10%) had pulmonary edema (Killip class III), and 47 (19%) had cardiogenic shock (Killip class IV). Respective mortality rates were 6%, 17%, 38%, and 81%. Although the overall mortality for acute MI has decreased since 1967, the Killip class on admission remains a powerful predictor of outcome among patients treated with reperfusion therapy.^{18,19} DeGeare and coworkers¹⁹ performed an analysis of 2654 patients with acute MI who were enrolled in three primary angioplasty trials. Patients in

Killip class IV were excluded. Increasing Killip class was associated with an increased need for intra-aortic balloon counterpulsation and a greater incidence of renal failure, major arrhythmias, and major bleeding. After controlling for confounding variables, the Killip class on admission remained a multivariate predictor of both in-hospital and 6-month mortality.

The physical examination also may provide clues to the diagnosis of causes of chest pain other than ACS. A pericardial friction rub may be audible in patients with pericarditis. Aortic dissection may be associated with diminished or absent pulses. Both diagnoses are important to exclude because they are contraindications to fibrinolytic therapy.

DIAGNOSTIC APPROACH

The American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines has published detailed recommendations for the diagnosis and management of patients with ACS.^{1,20-24} Conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective are categorized as Class I^{1,20} (not to be confused with Killip class I). Conditions for which there is conflicting evidence or divergence of opinion are categorized as Class II. The weight of evidence or opinion is in favor of usefulness or efficacy for Class IIa conditions, whereas usefulness or efficacy is less well established for Class IIb conditions. Class III conditions are those for which there is evidence or general agreement that a procedure/treatment is not useful or effective and may be harmful in some cases.

ELECTROCARDIOGRAM

The ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction include three Class I indications for an ECG.²⁰ The first is that all patients with chest discomfort or other symptoms suggestive of STEMI should have a 12-lead ECG within 10 minutes of arrival in the emergency department (and it should be interpreted by an experienced physician). The second is that serial ECGs should be performed at intervals of 5 to 10 minutes in patients with a nondiagnostic initial ECG if the patient remains symptomatic and there is a high clinical suspicion of STEMI. The third is that right-sided ECG leads should be obtained to screen for right ventricular MI in patients with inferior STEMI.

The electrocardiographic diagnosis of acute MI in the presence of a left bundle branch block (LBBB) is problematic.^{25,26} Angiographic studies have demonstrated a low prevalence of acute MI among patients with a new LBBB.²⁷⁻³⁰ Analysis of the Mayo Clinic's primary PCI database found that only 12 of 36 patients with a new LBBB and clinical symptoms suspicious for an MI met troponin criteria for an MI, resulting in emergency activation of the cardiac catheterization laboratory for a false-positive diagnosis of acute MI in two thirds of patients with a new LBBB.²⁸

Sgarbossa and associates³¹ devised an algorithm for the diagnosis of acute MI in patients with LBBB that used three electrocardiographic criteria: ≥ 1 mm ST segment elevation concordant with the QRS complex; ≥ 1 mm ST segment depression in leads V₁, V₂, or V₃; and ≥ 5 mm ST segment elevation discordant with the QRS complex. Several

subsequent studies investigated the utility of the so-called Sgarbossa criteria.^{26,29} A study that enrolled 83 patients with LBBB and symptoms suggestive of acute MI found that the ECG algorithm based on the Sgarbossa criteria had a sensitivity of only 10%.²⁶

Patients with an acute MI who present with an LBBB that is new or of indeterminate age have a worse prognosis than patients without an LBBB. A bundle branch block was present on the admission electrocardiogram in 4% of the patients with a suspected acute MI who were included in a meta-analysis of nine trials that randomized 58,600 patients to either a control group or fibrinolytic therapy.³² Mortality at 35 days for patients who were randomized to the control groups was greater among patients who presented with a bundle branch block (23.6%), compared with patients who had ST segment elevation in the anterior leads (16.9%) or inferior leads (8.4%), or ST segment depression 13.8%).³² Fibrinolytic therapy was associated with a 25% reduction in mortality among patients who presented with a bundle branch block on ECG.³² The publication did not provide information regarding the age of the bundle branch block or whether the meta-analysis was limited to patients with an LBBB or also included patients with a right bundle branch block.³² Among 3053 patients with an acute MI who were enrolled in the Primary Angioplasty in Myocardial Infarction (PAMI) trials, an LBBB was an independent predictor of in-hospital death (odds ratio 5.53; 95% confidence interval [CI] 1.89 to 16.1; $p = 0.002$).³³

Patients with LBBB and acute MI frequently have no chest pain at the time of presentation. Chest pain was not reported by 47% of the 29,585 patients with LBBB and acute MI who were enrolled in the National Registry of Myocardial (NRM) 2 registry.³⁴ Patients who presented without chest pain were less likely to receive aspirin or a β -blocker and four times less likely to receive reperfusion therapy (odds ratio 0.25).³⁴ This may explain why patients with acute MI and LBBB who presented without chest pain had a 47% greater in-hospital mortality rate than patients who presented with chest pain (27% versus 18%; $p < 0.001$).³⁴

A new or presumably new LBBB in patients with symptom onset within the prior 12 hours was designated as a Class I indication for either fibrinolytic therapy or primary percutaneous coronary intervention (PCI) in the guidelines for the management of acute MI that were issued by the American College of Cardiology/American Heart Association Task Force on Practice Guidelines in 2004.²⁰ According to the most recent revision of the practice guidelines for ST elevation MI, a new or presumably new LBBB “should not be considered diagnostic of acute MI in isolation.”²⁴ The risks of fibrinolytic therapy may be increased in patients with LBBB due to older age and a higher prevalence of hypertension. Therefore, the most prudent strategy in patients with LBBB and a suspected acute MI may be immediate coronary angiography, both to diagnose an acute coronary artery occlusion and to eliminate the risk of fibrinolytic therapy in patients who cannot benefit from it (i.e., patients with a non-ST segment elevation MI or a non-cardiac condition). A more detailed discussion of the management of patients with LBBB and suspected MI can be found in an excellent review article that was published in 2012.²⁵

The ECG provides additional important information in patients with acute MI. Patients with acute inferior STEMI

who have ST segment depression in the precordial leads have larger infarctions, more complications post-MI, and a higher mortality rate than patients without precordial ST segment depression.³⁵ The presence of Q waves in the infarct territory on the initial ECG is an independent predictor of greater 30-day mortality irrespective of the infarct location or time between symptom onset and administration of fibrinolytic therapy.³⁶ Nevertheless, substantial myocardial salvage is possible despite Q waves on the initial ECG.³⁷

The electrocardiographic leads with ST segment elevation have been correlated with occlusions of the left anterior descending (LAD), left circumflex, or right coronary arteries.^{38,39} The number of leads with ST segment elevation before reperfusion therapy and the degree of resolution of ST segment elevation after either fibrinolytic therapy or primary angioplasty confer useful prognostic information. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI) trial investigators reported that in-hospital mortality was directly related to the number of leads with ST segment elevation for both the patients treated with streptokinase and the control group.⁴⁰ Treatment with streptokinase significantly reduced in-hospital mortality among patients with ST segment elevation in four or more leads, but not among patients with ST segment elevation that was confined to two or three leads⁴⁰ (Fig. 30.2). Early ST segment recovery is associated with improved infarct zone wall motion⁴¹ and greater myocardial salvage as assessed by technetium-99m sestamibi scintigraphy.⁴² Also, resolution of ST segment elevation within 90 minutes after either primary angioplasty or fibrinolytic therapy identifies patients with lower mortality at 30 days and 1 year and 5 years after STEMI.⁴³⁻⁴⁶ Continuous ECG monitoring is customary for the detection of arrhythmias and conduction abnormalities.

Figure 30.2 In-hospital mortality among patients randomized to the streptokinase (SK) and control groups in the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-1) trial. Treatment with streptokinase significantly reduced in-hospital mortality among patients with ST segment elevation in four or more leads, but not among patients with ST segment elevation that was confined to two or three leads. NS, not significant. (Data from Mauri F, Gasparini M, Barbonaglia L, et al: Prognostic significance of the extent of myocardial injury in acute myocardial infarction treated by streptokinase (the GISSI trial). *Am J Cardiol* 1989;63:1291-1295.)

Figure 30.3 ST segment elevation in various conditions. *Tracing 1*, Left ventricular hypertrophy. *Tracing 2*, Left bundle branch block. *Tracing 3*, Acute pericarditis. *Tracing 4*, Hyperkalemia. *Tracing 5*, Acute anteroseptal infarction. *Tracing 6*, Acute anteroseptal infarction and right bundle branch block. *Tracing 7*, Brugada syndrome. (From Wang K, Asinger RW, Marriott HJ: ST-segment elevation in conditions other than acute myocardial infarction. *N Engl J Med* 2003;349:2128-2135.)

It is important to recognize that ST segment elevation occurs in numerous conditions other than acute MI.⁴⁷ The list includes left ventricular hypertrophy, LBBB, acute pericarditis, hyperkalemia, Brugada syndrome, pulmonary embolism, and left ventricular apical ballooning syndrome (takotsubo cardiomyopathy)^{47,48} (Fig. 30.3).

CARDIAC ENZYMES

Myocardial necrosis is accompanied by the release of several biochemical markers in circulating blood, including creatine kinase, myoglobin, troponins T and I, and lactate dehydrogenase. As noted previously, a typical rise and gradual fall of troponin or more rapid rise and fall of CK-MB are required to diagnose an acute, evolving, or recent MI.² The ACC/AHA guidelines, however, stress that decisions such as initiation of reperfusion therapy for patients with ST segment elevation and symptoms of STEMI should not be delayed until the results of serum cardiac biomarkers are available.⁴⁹

Although troponin has become the preferred biomarker for myocardial necrosis, numerous other causes of an

elevated troponin have been recognized, and several may be associated with chest pain or ST segment elevation.⁵⁰ An elevated troponin in patients with pulmonary embolism is associated with right ventricular dysfunction and an increased risk of hypotension and death.⁵¹⁻⁵³ Elevated cardiac troponin also has been reported in patients with acute pericarditis, and patients with ST segment elevation were more likely to have an elevated troponin.⁵⁴

ECHOCARDIOGRAPHY

Echocardiography may be a useful diagnostic tool under a variety of circumstances. A transesophageal echocardiogram may be useful to differentiate STEMI from aortic dissection. Both transthoracic and transesophageal echocardiography are useful in patients with congestive heart failure (CHF) or hypotension to evaluate left and right ventricular function, to rule out cardiac tamponade, and to diagnose ventricular septal rupture or mitral regurgitation (MR). Mitral regurgitation is frequent among patients with uncomplicated MI. Color Doppler echocardiography was performed within 48 hours of admission in a series of 417

consecutive patients with acute MI.⁵⁵ Mild mitral regurgitation was present in 121 patients (29%), moderate mitral regurgitation in 21 (5%), and severe mitral regurgitation in 4 (1%).⁵⁵ Patients with any mitral regurgitation had higher 30-day and 1-year mortality rates, and mitral regurgitation was independently associated with increased 1-year mortality.⁵⁵ Echocardiography performed within 30 days after acute MI revealed mitral regurgitation in 50% of a cohort of 773 patients.⁵⁶ Cardiac auscultation did not detect a murmur in 54% of patients with mild and 31% of patients with moderate or severe mitral regurgitation.⁵⁶ Among 30-day survivors of an MI, during a mean follow-up period of 4.7 years moderate or severe mitral regurgitation detected by echocardiography within 30 days of MI was associated with a 55% increase in the relative risk (RR) of death independent of age, gender, left ventricular ejection fraction (EF), and Killip class.⁵⁶

HEMODYNAMIC MONITORING

The value of pulmonary artery catheterization in critically ill patients has been questioned.⁵⁷ The evidence base regarding the impact of pulmonary artery catheters on outcome in patients with acute MI is limited to retrospective studies because pulmonary artery catheterization in patients with acute MI has not been evaluated in a prospective, randomized, controlled trial.⁵⁸⁻⁶⁰ Cohen and associates⁶⁰ performed a retrospective analysis of pulmonary artery catheterization in patients with ACS who were enrolled in two large international randomized clinical trials, Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries (GUSTO) IIb and GUSTO III. The study compared the outcomes in 735 patients who received PA catheters with those in 25,702 patients who did not. Except for patients with cardiogenic shock, mortality at 30 days was significantly greater among patients who received pulmonary artery catheters, both before and after adjustment for baseline differences and subsequent events that may have prompted insertion of a pulmonary artery catheter.

According to the ACC/AHA Guidelines, the Class I indications for pulmonary artery catheter monitoring are (1) progressive hypotension that either is unresponsive to fluid administration or is developing in a patient in whom fluid administration is contraindicated and (2) a suspected mechanical complication, such as a VSD or papillary muscle rupture, if an echocardiogram has not been performed.²⁰ Intra-arterial pressure monitoring is recommended for patients with systolic blood pressure less than 80 mm Hg, patients with cardiogenic shock, and patients receiving vasopressor and inotropic drugs.²⁰

Access site bleeding is a major risk of central line insertion in patients who have received fibrinolytic drugs. The femoral route is preferred, and noncompressible sites, such as the subclavian vein, are relatively contraindicated.

DIAGNOSTIC CARDIAC CATHETERIZATION AND CORONARY ANGIOGRAPHY

Conditions other than STEMI can cause ST segment elevation. Pericarditis, for example, is a relative contraindication to fibrinolytic therapy because of the risk of intrapericardial bleeding and tamponade. Therefore, urgent coronary angiography and primary angioplasty if indicated would be preferable to intravenous fibrinolytic therapy if there is any

suspicion of pericarditis. Similarly, diagnostic cardiac catheterization should be performed if clinical findings and noninvasive studies are unable to differentiate aortic dissection from acute MI.

Right heart catheterization and contrast ventriculography can provide useful diagnostic information in patients with suspected acute MI. Measurement of right heart pressures is useful in patients with suspected right ventricular MI and in patients with hypotension. Measurement of the oxygen content of blood in the right atrium and pulmonary artery is useful in patients with a suspected VSD. A contrast left ventriculogram provides an assessment of regional and global left ventricular function and the competence of the mitral valve. Left ventriculography was performed during the index cardiac catheterization in 1976 (95%) of 2082 patients with acute MI who were enrolled in the Controlled Abciximab and Device Investigation to Lower Angioplasty Complications (CADILLAC) trial.⁶¹ Mild mitral regurgitation was present in 192 patients (9.7%), and moderate or severe mitral regurgitation was present in 58 patients (2.9%). Mitral regurgitation was not detected by physical examination in 50% of a cohort of 50 patients with acute MI and moderately severe or severe mitral regurgitation that was demonstrated by left ventriculography.⁶²

Numerous studies have addressed the role of routine early angioplasty after fibrinolytic therapy.⁶³⁻⁶⁸ A prospective cohort study of 21,912 patients with a first acute MI concluded that revascularization within 14 days of the acute MI was associated with a significant reduction in 1-year mortality (RR 0.47; 95% CI 0.37 to 0.60; $p < 0.001$).⁶³ Several randomized trials have shown beneficial effects of a routine invasive strategy immediately after fibrinolysis,⁶⁵ within 24 hours after fibrinolysis,⁶⁶ and 1 to 6 weeks after acute MI.⁶⁷ The most recent trials have provided support for the practice of routine early angioplasty after fibrinolytic therapy.⁶⁸⁻⁷⁰ The Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) enrolled 1059 patients with a “high-risk” STEMI who received fibrinolytic therapy at centers that did not have the capability to perform PCI.⁶⁸ The patients were randomized to either “standard” treatment (including rescue PCI or delayed angiography) or immediate transfer to another hospital for PCI within 6 hours after fibrinolysis. The primary end point—the composite of death, reinfarction, recurrent ischemia, new or worsening congestive heart failure, or cardiogenic shock within 30 days—occurred in 11% of the patients who were assigned to routine early PCI, compared with 17.2% of the patients who were assigned to standard treatment (RR 0.64; 95% CI 0.47 to 0.87; $p = 0.004$). Borgia and colleagues⁶⁹ performed a meta-analysis of seven randomized, controlled trials that compared routine early PCI after successful fibrinolysis with PCI only for patients without evidence of reperfusion (rescue PCI). After a follow-up period of 30 days routine early PCI after successful fibrinolysis reduced the rates of reinfarction (odds ratio 0.55; 95% CI 0.36 to 0.82; $p = 0.003$), the combined end point of death and reinfarction (odds ratio 0.65; 95% CI 0.49 to 0.88; $p = 0.004$), and recurrent ischemia (odds ratio 0.25; 95% CI 0.13 to 0.49; $p < 0.001$). The benefits of early PCI persisted after 6 to 12 months of follow-up. D’Souza and associates⁷⁰ performed a meta-analysis of eight randomized trials that compared

routine early PCI with ischemia-driven PCI after fibrinolysis in patients with STEMI. PCI within 24 hours after fibrinolytic therapy was associated with less re-infarction and recurrent ischemia.

The 2004 and 2007 Focused Update of the ACC/AHA Guidelines for the management of patients with STEMI include five Class I recommendations, two Class IIa recommendations, and one Class IIb recommendation for coronary angiography in patients with acute MI^{20,21} (Box 30.1). Coronary angiography is recommended in survivors of STEMI who are candidates for revascularization therapy with spontaneous ischemia, intermediate-risk or high-risk findings on noninvasive testing, hemodynamic or electrical instability, mechanical defects, prior revascularization, or high-risk clinical features.

APPROACH TO MANAGEMENT

Figure 30.4 presents an algorithm for the treatment of acute STEMI.

GENERAL CONSIDERATIONS

Patients who present to the emergency department with an acute MI will usually be diagnosed and treated before admission to the intensive care unit (ICU). It is not unusual, however, for STEMI to occur in patients receiving ICU treatment for other conditions, such as gastrointestinal bleeding or respiratory failure, or undergoing surgical procedures. As in the patients who present to an emergency department (ED), prompt performance and interpretation of an ECG constitute a critical initial step in management. Continuous ECG monitoring for arrhythmias is routinely practiced. Patients usually are advanced from nothing-by-mouth (NPO [*nil per os*]) status to clear liquids to a low-fat, low-cholesterol diet as tolerated. Stool softeners should be employed to prevent the hemodynamic effects of constipation.

OXYGEN

The effects of supplemental oxygen on ischemic injury was studied by Madias and colleagues.⁷¹ Seventeen patients with acute anterior MI who were not in cardiogenic shock underwent precordial ST segment mapping before and after inhalation of 100% oxygen for 1 hour. The mean arterial partial pressure of oxygen increased from 70 mm Hg on room air to 278 mm Hg during oxygen inhalation. During oxygen inhalation there was a 16% reduction in the sum of all ST segment elevation, with reversion to baseline after oxygen was discontinued. Two hundred patients with suspected acute MI were enrolled in a double-blind, randomized trial of supplemental oxygen versus compressed air.⁷² No apparent benefit was observed for oxygen therapy, and the mortality rate was higher in the oxygen group than in the control group (9/80 versus 3/77; $p = \text{NS}$). A meta-analysis of 3 trials that enrolled 387 patients found that the pooled relative risk of death for patients who were treated with oxygen compared to air was 2.88 (95% CI 0.88 to 9.83).²¹ Hyperoxia during inhalation of high concentrations of oxygen causes an increase in coronary vascular resistance and a decrease in coronary blood flow.⁷³

Although supplemental oxygen is routinely administered to patients with STEMI, according to the ACC/AHA guidelines the only Class I indication for this intervention is an

Box 30.1 ACC/AHA Practice Guidelines for Invasive Evaluation after ST Segment Elevation Myocardial Infarction (STEMI)

Class I

1. Coronary arteriography should be performed in patients with spontaneous episodes of myocardial ischemia or episodes of myocardial ischemia provoked by minimal exertion during recovery from STEMI.
2. Coronary arteriography should be performed for intermediate- or high-risk findings on noninvasive testing after STEMI.
3. Coronary arteriography should be performed if the patient is sufficiently stable before definitive therapy for a mechanical complication of STEMI, such as acute MR, VSR, pseudoaneurysm, or left ventricular aneurysm.
4. Coronary arteriography should be performed in patients with persistent hemodynamic instability.
5. Coronary arteriography should be performed in survivors of STEMI who had clinical heart failure during the acute episode but subsequently demonstrated well-preserved left ventricular function.

Class IIa

1. It is reasonable to perform coronary arteriography when STEMI is suspected to have occurred by a mechanism other than thrombotic occlusion of an atherosclerotic plaque. Such mechanisms would include coronary embolism, certain metabolic or hematologic diseases, and coronary artery spasm.
2. Coronary arteriography is reasonable in STEMI patients with any of the following: diabetes mellitus, left ventricular EF less than 0.40, CHF, prior revascularization, or life-threatening ventricular arrhythmias.

Class IIb

1. Coronary arteriography may be considered as part of an invasive strategy for risk assessment after fibrinolytic therapy or for patients not undergoing primary reperfusion.

Class III

1. Coronary arteriography should not be performed in survivors of STEMI who are thought not to be candidates for coronary revascularization.

CHF, congestive heart failure; EF, ejection fraction; MR, mitral regurgitation; VSR, ventricular septal rupture.

Modified slightly from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). Circulation 2004;110:e82-e292; Antman EM, Hand M, Armstrong PW, et al: 2007 focused update of the ACC/AHA 2004 guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing group to review new evidence and update the ACC/AHA 2004 guidelines for the management of patients with ST-elevation myocardial infarction). J Am Coll Cardiol 2008;51:210-247.

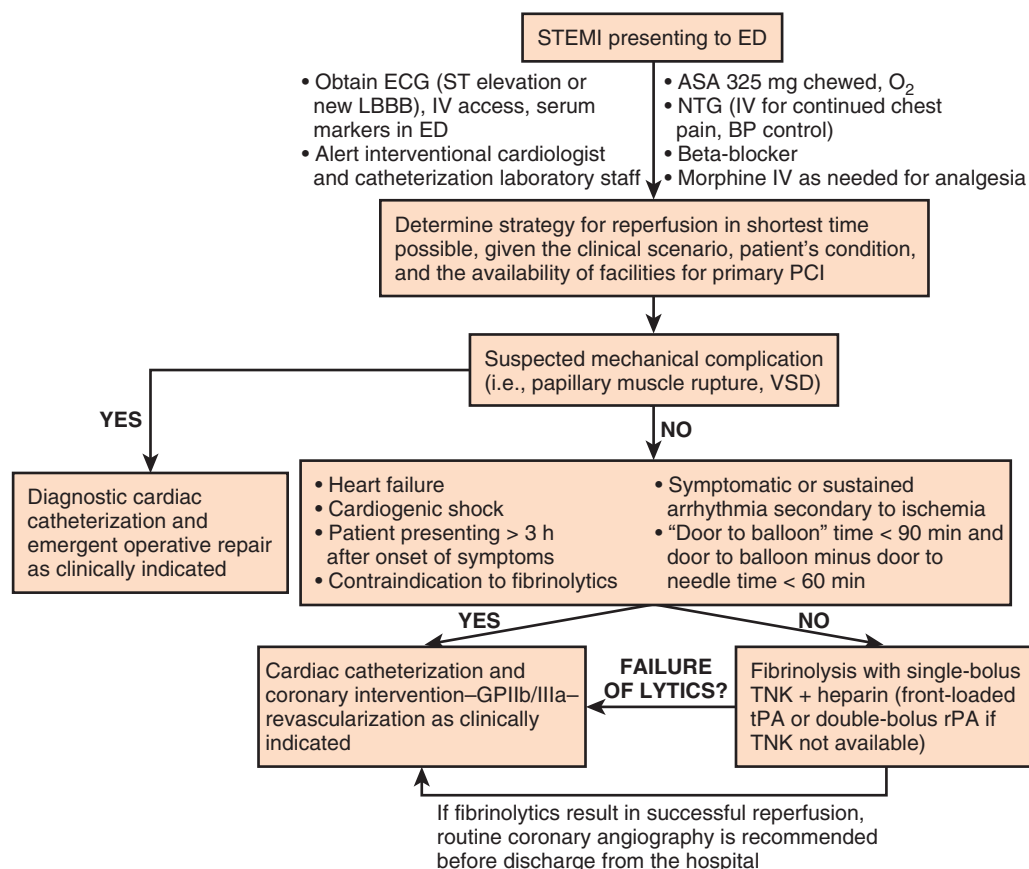

Figure 30.4 Algorithm for the treatment of acute ST segment elevation myocardial infarction (STEMI). *Note:* Nitroglycerin should be used with caution in patients with inferior wall myocardial infarction with possible right ventricular involvement. Nitroglycerin should be avoided altogether in hypotensive patients. ASA, acetylsalicylic acid (aspirin); BP, blood pressure; ECG, electrocardiogram; ED, emergency department; IV, intravenous; LBBB, left bundle branch block; MSO₄, morphine sulfate; NTG, nitroglycerin; PTCA, percutaneous transluminal coronary angioplasty; rPA, recombinant plasminogen activator (alteplase); TNK, tenecteplase; tPA, tissue plasminogen activator; VSD, ventricular septal defect.

arterial oxygen saturation less than 90%.²⁰ The guidelines also include a Class IIa indication: “It is reasonable to administer supplemental oxygen to all patients with uncomplicated STEMI during the first 6 hours.”²⁰ Randomized, controlled trials of oxygen therapy in patients with STEMI are planned.⁷⁴

ANALGESIA AND SEDATION

Relief of pain is an important goal in patients with acute MI. The 2007 Focused Update of the ACC/AHA 2004 Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction included several recommendations regarding analgesic drugs.²¹ According to the guidelines, morphine sulfate is the analgesic of choice for the management of pain associated with STEMI, and pain associated with STEMI is a Class I indication for intravenous morphine.²¹ There are no published randomized trials of morphine therapy in patients with acute MI. An analysis of the CRUSADE registry, however, revealed that use of morphine was associated with a 50% higher mortality in patients with NSTEMI even after risk adjustment.⁷⁵ One proposed mechanism of morphine’s adverse effect is opioid-induced cortisol deficiency.⁷⁶ Until additional data become available, it may be prudent to limit the use of morphine to patients with persistent pain despite treatment with nitrates and a β -adrenergic antagonist.

The abundant evidence that nonsteroidal anti-inflammatory drugs (NSAIDs) have adverse effects in patients with cardiovascular disease has been reviewed in great detail in multiple publications, including a scientific statement from the American Heart Association and a meta-analysis of 31 trials that enrolled 116,429 patients.⁷⁷⁻⁷⁹ A Danish study of 58,432 patients who were hospitalized for a first-time acute MI between 1995 and 2002 found that treatment with either a selective cyclooxygenase-2 inhibitor or a nonselective NSAID after discharge from the hospital significantly increased the risk of death.⁸⁰ A subsequent study by the same investigators found that even short-term treatment with NSAIDs was associated with an increased risk of death and recurrent MI in patients with a prior MI.⁸¹ One possible explanation for the adverse cardiovascular effects of NSAIDs is inhibition of the clinical benefits of aspirin. An analysis of the Physicians’ Health Study concluded that there was greater than a twofold increased risk of a first MI among healthy male U.S. physicians who were randomized to aspirin and also took other NSAIDs on > 60 days per year.⁸² An important pharmacologic study demonstrated that inhibition of platelet aggregation by aspirin was blocked when ibuprofen was administered before aspirin.⁸³ The 2007 Focused Update of the ACC/AHA 2004 Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction included two new recommendations regarding

both nonselective and cyclooxygenase-2 selective NSAIDs: a Class I recommendation that patients routinely taking NSAIDs (except for aspirin) before a STEMI should have those agents discontinued at the time of presentation with STEMI; and a Class III recommendation that NSAIDs (except for aspirin) “should not be administered during hospitalization for STEMI because of the increased risk of mortality, reinfarction, hypertension, heart failure, and myocardial rupture associated with their use.”²¹

NITRATES

The ability of sublingual or intravenous nitroglycerin to relieve chest pain in patients with acute MI is well documented.⁸⁴ The beneficial physiologic effects of nitrates include vasodilation of peripheral arteries and veins, causing reductions in pulmonary capillary wedge pressure (PCWP), mean arterial pressure, and peripheral vascular resistance, thereby decreasing left ventricular preload and afterload and myocardial oxygen demand.⁸⁵ Also, vasodilation of the coronary arteries may improve myocardial oxygen supply, especially in patients with a component of coronary spasm.⁸⁶ Severe hypotension and bradycardia have been observed after administration of either sublingual or intravenous nitroglycerin in patients with acute MI.⁸⁷ Patients with right ventricular MI may experience severe hypotension during administration of nitroglycerin because adequate right ventricular preload is required to maintain cardiac output. Nitroglycerin is contraindicated in patients who have taken phosphodiesterase inhibitors because they potentiate nitroglycerin-induced hypotension.⁸⁸

There are two Class I indications for nitroglycerin in patients with STEMI. Sublingual nitroglycerin (0.4 mg) every 5 minutes for a total of three doses is recommended for relief of ischemic discomfort.²⁰ Intravenous nitroglycerin is indicated for relief of ongoing ischemic discomfort, control of hypertension, or management of pulmonary congestion.²⁰ It has been proposed that intravenous nitroglycerin may limit myocardial infarct size and expansion.⁸⁹ Two large clinical trials, however, were unable to demonstrate significant improvements in mortality by the prolonged administration of nitroglycerin after acute MI.^{90,91} The GISSI-3 trial enrolled 19,394 patients with acute MI.⁹⁰ Patients who were randomized to treatment with nitroglycerin received intravenous nitroglycerin for 24 hours, followed by transdermal nitroglycerin for 6 weeks.⁹⁰ Nitroglycerin did not reduce the 6-week rate of death or clinical heart failure. The Fourth International Study of Infarct Survival (ISIS-4) enrolled 58,050 patients with suspected acute MI in a $2 \times 2 \times 2$ factorial study that included randomization to isosorbide mononitrate 60 mg daily or placebo for 28 days.⁹¹ No significant effect of nitroglycerin on mortality was found after 5 weeks or 1 year.

Several studies have investigated the effect of another nitrate, nitroprusside, on hemodynamics and outcome in patients with acute MI.⁹²⁻⁹⁵ Intravenous nitroprusside reduced PCWP and increased cardiac index in patients with acute MI.^{92,93} A comparison of intravenous nitroprusside with intravenous nitroglycerin in 10 patients with acute anterior MI demonstrated that ST segment elevation increased during infusion of nitroprusside, whereas it decreased during infusion of nitroglycerin.⁹² Experimental data indicate that nitroprusside may exacerbate myocardial

ischemia or injury by redistribution of myocardial blood flow from ischemic to nonischemic zones.⁹² A Veterans Administration Cooperative Study enrolled 812 patients with acute MI and a PCWP greater than 12 mm Hg in a double-blind, randomized trial of nitroprusside infused for 48 hours.⁹⁵ Compared with the placebo group, mortality at 13 weeks was increased by nitroprusside in patients whose infusions started within 9 hours of the onset of pain. A smaller European trial randomized 328 patients with acute MI to infusion of nitroprusside or 5% glucose.⁹⁴ The trial was terminated when 1-week mortality in the control group was significantly greater than in the nitroprusside group (10.9% versus 3.1%; $p < 0.05$). The use of nitroprusside in patients with acute MI should probably be reserved for patients with severe hypertension that is unresponsive to treatment with intravenous nitroglycerin.

ASPIRIN

The Second International Study of Infarct Survival (ISIS-2) provided definitive evidence that aspirin reduces mortality in patients with acute MI.⁹⁶ The study used a 2×2 factorial design to randomize 17,187 patients to four treatment groups: streptokinase, aspirin 160 mg daily for 1 month, both, or neither. Aspirin reduced the rate of in-hospital reinfarction both in the patients who received streptokinase and in the patients who did not receive fibrinolytic therapy. At 35 days, the vascular-cause mortality rate was 9.4% among the patients in the aspirin treatment group patients, compared with 11.8% among those in the placebo group, representing a 23% reduction ($p < 0.00001$). Aspirin also significantly reduced all-cause mortality. Also, the combination of aspirin and streptokinase reduced mortality more than did either agent alone. The effects of the initial dose of aspirin on short-term outcomes after fibrinolytic therapy were tested by analyzing the outcomes of 48,422 patients with STEMI who were enrolled in two large clinical trials, Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) I and GUSTO III.⁹⁷ Compared with an initial dose of 162 mg, an initial dose of 325 mg was associated with a significant increase in moderate or severe bleeding in-hospital, but the rates of reinfarction and death at 24 hours, 7 days, and 30 days were not significantly different.⁹⁷ Nevertheless, the ACC/AHA Practice Guidelines for the Management of Patients with STEMI recommend that patients who present with acute STEMI who have not taken aspirin should receive 162 to 325 mg of non-enteric-coated aspirin, and the aspirin tablets should be chewed.²⁰ Also, the 2011 update of the guidelines for PCI include a Class IIa recommendation that “After PCI, it is reasonable to use 81 mg of aspirin per day in preference to higher maintenance doses.”⁹⁸

Reocclusion of a patent infarct artery after successful fibrinolytic therapy is associated with higher in-hospital mortality, reduced event-free survival after hospital discharge, and long-term impairment of regional and global left ventricular function.⁹⁹⁻¹⁰² There are conflicting opinions regarding aspirin's effect on reocclusion of an infarct artery.^{103,104} The Antithrombotics in the Prevention of Reocclusion in Coronary Thrombolysis (APRICOT) study randomized 300 patients with an open infarct artery within 48 hours after fibrinolysis to three treatment groups: aspirin 325 mg daily, warfarin, or placebo.¹⁰⁵ Cardiac

catheterization was performed 3 months later in 248 patients. The reocclusion rates were not significantly different: 32% (24/74) with placebo, 30% (24/81) with warfarin, and 25% (23/93) with aspirin. A pooled analysis of published studies estimated that the incidence of reocclusion after streptokinase or tissue plasminogen activator (tPA) is approximately 11% with aspirin, compared with 25% without aspirin.¹⁰³

INHIBITORS OF THE PLATELET P2Y₁₂ RECEPTOR

The combination of aspirin with inhibitors of the platelet P2Y₁₂ receptor has been shown to be superior to aspirin alone in patients with a STEMI.¹⁰⁶⁻¹⁰⁸ The Clopidogrel as Adjunctive Reperfusion Therapy (CLARITY) study enrolled 3491 patients who received fibrinolytic therapy for STEMI and randomized them to receive clopidogrel 75 mg daily or placebo in a double-blind fashion.¹⁰⁶ Coronary angiography performed at a median of 84 hours after randomization in each group demonstrated an occluded IRA in 18.4% of the placebo group patients, compared with 11.7% of the clopidogrel group patients ($p < 0.001$). PCI was performed during the index hospitalization in 1863 (53.4%) of the patients who were enrolled in the CLARITY trial.¹⁰⁸ The combined incidence of cardiovascular death, recurrent MI, or stroke from PCI to 30 days after randomization was significantly lower among patients who were treated with clopidogrel and aspirin compared with the patients who received aspirin alone (3.6% versus 6.2%; adjusted odds ratio 0.54; 95% CI 0.35 to 0.85; $p = 0.008$).¹⁰⁸ The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) randomized 45,852 patients with suspected acute MI to receive treatment with aspirin 162 mg daily plus clopidogrel 75 mg daily or placebo.¹⁰⁷ The in-hospital mortality rate was significantly lower for the clopidogrel group than for the placebo group (7.5% versus 8.1%; $p = 0.03$). The CLARITY study used a clopidogrel loading dose of 300 mg; the COMMIT study did not employ a loading dose.

A multivariate-weighted logistic regression analysis of the outcomes of 8429 STEMI patients who were enrolled in 26 randomized clinical trials concluded that pretreatment with a loading dose of clopidogrel before primary PCI was an independent predictor of coronary artery patency before PCI (odds ratio 1.51; 95% CI 1.31 to 1.74; $p < 0.0001$) and decreased mortality after PCI (odds ratio 0.57; 95% CI 0.38 to 0.85; $p = 0.0055$).¹⁰⁹ Among patients with STEMI who were enrolled in the Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) trial and underwent primary PCI, a clopidogrel loading dose of 600 mg ($n = 2158$), compared with 300 mg ($n = 1153$) was associated with significantly lower 30-day rates of mortality, reinfarction, and stent thrombosis, and was an independent predictor of freedom from major adverse cardiac events at 30 days.¹¹⁰

Prasugrel, another inhibitor of the platelet P2Y₁₂ receptor, was studied in patients with ACS, including patients with STEMI, in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38.^{111,112} The trial randomized 3534 patients with STEMI who were undergoing either primary PCI (PCI within 12 hours of symptom onset) or secondary PCI (PCI between 12 hours and 14 days after symptom onset) to either

prasugrel (60 mg loading dose and 10 mg/day maintenance dose) or clopidogrel (300 mg loading dose and 75 mg maintenance dose) for 6 to 15 months.¹¹² The primary end point of cardiovascular death, nonfatal MI, or nonfatal stroke, was significantly less frequent at both 30 days and 15 months among patients who were randomized to prasugrel compared with patients who were randomized to clopidogrel.¹¹²

Ticagrelor, an inhibitor of the platelet P2Y₁₂ receptor, was studied in patients with ACS, including patients with STEMI, in the Study of Platelet Inhibition and Patient Outcomes (PLATO).^{113,114} The trial randomized 7544 patients with STEMI who were undergoing primary PCI to either ticagrelor (180 mg loading dose and 90 mg twice daily maintenance dose) or clopidogrel (300 mg loading dose and 75 mg maintenance dose) for 6 to 12 months.¹¹⁴ Compared with clopidogrel, treatment with ticagrelor reduced several secondary end points, including MI (hazard ratio 0.80; $p = 0.03$), total mortality (hazard ratio 0.82; $p = 0.05$), and definite stent thrombosis (hazard ratio 0.66; $p = 0.03$); major bleeding was not significantly different (hazard ratio 0.98; $p = 0.76$).¹¹⁴

The 2007 and 2009 focused updates of the ACC/AHA Practice Guidelines for the Management of Patients with STEMI include several new recommendations regarding antiplatelet therapy (Box 30.2).^{21,22} The Class I recommendations include the following: (1) clopidogrel 75 mg/day orally should be added to aspirin in patients with STEMI regardless of whether they undergo reperfusion with fibrinolytic therapy or do not receive reperfusion therapy. Treatment with clopidogrel should continue for at least 14 days. (2) A loading dose of a P2Y₁₂ inhibitor is recommended for STEMI patients for whom PCI is planned. The options include clopidogrel, prasugrel, and ticagrelor. Prasugrel is contraindicated in patients with a history of TIA or stroke and active pathologic bleeding. Also, prasugrel should not be administered to patients older than age 75 because of an increased risk of fatal and intracranial bleeding. Finally, the maintenance dose of prasugrel should be reduced to 5 mg daily in patients who weigh less than 60 kg.

ANTICOAGULANT THERAPY

The rationale for anticoagulant therapy in patients with STEMI includes promotion of infarct artery patency, and prevention of deep vein thrombosis, pulmonary embolism, left ventricular mural thrombus, and cerebral embolism. Left ventricular mural thrombus formation after acute MI occurs more commonly after anterior than nonanterior wall MI and is associated with an increased risk of systemic embolization.^{115,116} Data conflict regarding the incidence of left ventricular thrombus in patients who receive reperfusion therapy. The GISSI-2 study, in which all patients received fibrinolytic therapy, observed left ventricular thrombi in 51 of 180 consecutive patients with a first anterior acute MI who underwent serial echocardiography within 48 hours after the onset of symptoms and before hospital discharge.¹¹⁷ Another study, however, detected left ventricular thrombi in only 6.4% of patients with acute anterior MI who underwent echocardiography on days 1, 14, and 90 after MI.¹¹⁸ A double-blind, randomized trial compared a 10-day course of high-dose subcutaneous UFH (12,500 units every 12 hours) with low-dose subcutaneous UFH (5000 units every 12

Box 30.2 ACC/AHA Practice Guidelines for Antiplatelet Therapy for Patients Undergoing PCI

Class I

1. Patients already taking daily aspirin therapy should take 81 mg to 325 mg before PCI.
2. Patients not on aspirin therapy should be given nonenteric aspirin 325 mg before PCI.
3. After PCI, use of aspirin should be continued indefinitely.
4. A loading dose of a P2Y₁₂ receptor inhibitor should be given to patients undergoing PCI with stenting. Options include the following:
 - a. Clopidogrel 600 mg; the loading dose of clopidogrel for patients undergoing PCI after fibrinolytic therapy should be 300 mg within 24 hours and 600 mg more than 24 hours after receiving fibrinolytic therapy
 - b. Prasugrel 60 mg
 - c. Ticagrelor 180
5. The duration of P2Y₁₂ receptor inhibitor therapy should be as follows:
 - a. In patients receiving a stent (BMS or DES) during PCI for ACS, P2Y₁₂ inhibitor therapy should be given for at least 12 months. Options include clopidogrel 75 mg daily, prasugrel 10 mg daily, and ticagrelor 90 mg twice daily.
6. In patients taking P2Y₁₂ receptor inhibitor therapy for whom CABG is planned and can be delayed, it is recommended that the drug be discontinued to allow for dissipation of the antiplatelet effect. The period of withdrawal should be at least 5 days in patients receiving clopidogrel or ticagrelor, and at least 7 days in patients receiving prasugrel, unless the need for revascularization or the net benefit of the of P2Y₁₂ receptor inhibitor outweighs the potential risks of excess bleeding.

Class IIa

1. After PCI, it is reasonable to use aspirin 81 mg per day in preference to higher maintenance doses.
2. If the risk of morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of P2Y₁₂ inhibitor therapy after stent implantation, earlier discontinuation of P2Y₁₂ inhibitor therapy is reasonable.

Class IIb

1. Continuation of dual antiplatelet therapy beyond 12 months may be considered in patients undergoing DES implantation.

Class III

1. Prasugrel should not be administered to patients with a prior history of stroke or transient ischemic attack.

ACS, acute coronary syndrome; BMS, bare metal stent; CABG, coronary artery bypass graft; DES, drug-eluting stent; PCI, percutaneous coronary intervention

Modified from Levine GN, Bates ER, Blankenship JC, et al: 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Society for Cardiovascular Angiography and Interventions. *J Am Coll Cardiol* 2011;58:e44-e122.

hours) in the prevention of left ventricular thrombus in 221 patients with acute anterior MI who did not receive fibrinolytic therapy.¹¹⁹ Echocardiography 10 days after MI demonstrated left ventricular thrombi in 10 of 95 patients (11%) in the high-dose group and in 28 of 88 patients (32%) in the low-dose group ($p = 0.0004$). A meta-analysis of seven studies that enrolled 270 patients suggests that systemic anticoagulation in patients with mural thrombi reduces embolic complications.¹¹⁵

Clinical trials have evaluated both subcutaneous and intravenous unfractionated heparin (UFH) in patients with acute MI who were treated with various fibrinolytic agents. Randomized, controlled clinical trials have shown that adjunctive therapy with intravenous UFH increases the patency of the IRA after administration of tPA.^{120,121} A meta-analysis that included 68,000 patients who were enrolled in randomized trials that compared UFH plus aspirin with aspirin alone showed that only 5 lives were saved per 1000 patients who received UFH in addition to streptokinase.¹²² The meta-analysis was heavily influenced by two studies, GISSI-2¹²³ and ISIS-3,^{124,125} that enrolled 62,067 patients who were randomly assigned to receive fibrinolytic therapy plus either aspirin alone or aspirin plus subcutaneous UFH. Another meta-analysis was limited to six randomized controlled trials that enrolled 1735 patients who received either intravenous UFH or no heparin after fibrinolytic therapy.¹²⁶ The analysis found that the addition of intravenous UFH to tPA or streptokinase had insignificant effects on mortality and reinfarction, but the risk of bleeding was significantly increased.¹²⁶

Several randomized clinical trials¹²⁷⁻¹³¹ and meta-analyses^{132,133} have been performed to compare low-molecular-weight heparin (LMWH) with placebo or UFH as adjuncts to fibrinolytic therapy in patients with STEMI. A meta-analysis of 16,943 patients who were enrolled in four randomized trials revealed that the end points of death or reinfarction at 7 days and at 30 days were significantly reduced by LMWH compared with placebo.¹³³ A meta-analysis of 7098 patients who were enrolled in six randomized trials revealed that LMWH, compared with UFH, reduced the rates of reinfarction during hospitalization and at 30 days, but the rates of death were not significantly different.¹³³ Neither meta-analysis included a subsequent trial, Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT)-TIMI 25, that compared enoxaparin, an LMWH, with UFH in patients with STEMI who received fibrinolytic therapy.^{129,130} The study was a double-blind, randomized comparison of enoxaparin given subcutaneously twice daily until hospital discharge versus intravenous UFH for 48 hours in 20,506 patients with STEMI. A fibrinolytic agent was received by 99.7% of the patients: 55% received alteplase, 20% received streptokinase, 19% received tenecteplase, and 5.5% received reteplase. The primary end point, death or nonfatal recurrent MI through 30 days, occurred in 12% of patients in the UFH group and in 9.9% of patients in the enoxaparin group ($p < 0.001$). The rates of major bleeding at 30 days were 1.4% in the UFH group and 2.1% in the enoxaparin group ($p < 0.001$), but the rates of intracranial hemorrhage were not significantly different (UFH 0.7%, enoxaparin 0.8%; $p = 0.14$). The enoxaparin strategy significantly reduced the risk of nonfatal MI at 1 year (5.7% versus 6.8%;

hazard ratio 0.82; 95% CI 0.73 to 0.92; $p < 0.001$).¹³⁰ One of the mechanisms underlying the benefit of low-molecular-weight heparin compared with unfractionated heparin may be improved patency of the infarct artery after fibrinolytic therapy.¹³¹

Fondaparinux, a synthetic pentasaccharide, is a factor Xa inhibitor that binds antithrombin and inhibits factor Xa. The Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) conducted two trials to evaluate fondaparinux in patients with ACS¹³⁴ and STEMI.^{135,136} The OASIS-6 trial was a randomized, double-blind comparison of fondaparinux 2.5 mg daily or control from days 3 through 9 in 12,092 patients with STEMI.¹³⁵ Forty-five percent of the patients received fibrinolytic therapy (streptokinase in 73%), 28.9% underwent primary PCI, and 23.7% did not receive any reperfusion therapy. The primary efficacy outcome, death or reinfarction at 30 days, was significantly lower in the fondaparinux group than in the control group (9.7% versus 11.2%; hazard ratio 0.86; 95% CI 0.77 to 0.96; $p = 0.008$). Also, fondaparinux significantly reduced the rates of death at day 9, day 30, and the end of the study (3 to 6 months). Significant heterogeneity in the effect of fondaparinux was observed in relation to the reperfusion strategy, with benefit observed in patients who received no reperfusion therapy or a fibrinolytic agent, but not in patients who underwent primary PCI. The rate of severe bleeding was not increased by fondaparinux.

A subgroup analysis of the OASIS-6 results was performed to compare the effects of fondaparinux with usual care (i.e., UFH or placebo) in patients with STEMI who did not receive any reperfusion therapy.¹³⁶ Fondaparinux significantly reduced the composite end point of death or recurrent MI, without an increase in severe bleeding or stroke, compared with UFH or placebo.¹³⁶

The dose of fondaparinux must be adjusted in patients with renal insufficiency, but adjustment for body weight is not necessary. The anticoagulant effect of the drug cannot be monitored by conventional clotting tests, such as the activated clotting time or partial thromboplastin time. Also, the relatively long half-life of fondaparinux, 17 to 21 hours, conceivably may be viewed as an impediment to early sheath removal and ambulation after cardiac catheterization. Because of the risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant during PCI, and an additional anticoagulant with antifactor IIa activity should be administered.²¹

Bivalirudin, a direct thrombin inhibitor, was compared with UFH plus glycoprotein IIb/IIIa inhibitors in 3602 patients with STEMI undergoing primary PCI in the HORIZONS-AMI trial.¹³⁷⁻¹³⁹ Compared with UFH plus glycoprotein IIb/IIIa inhibitors, anticoagulation with bivalirudin was associated with a reduced rate of net adverse clinical events and major bleeding at 30 days and 1 year.^{137,138} Also, treatment with bivalirudin was associated with both cardiac and all-cause mortality rates that were significantly lower after 30 days and 1 year.^{137,138} Among the 477 patients who were classified as “high risk,” the mortality rates at 1 year were 8.4% among patients treated with bivalirudin, compared with 15.9% among patients treated with UFH plus a glycoprotein IIb/IIIa inhibitor ($p = 0.01$).¹³⁹

According to the updated recommendations for the use of anticoagulants as ancillary therapy to reperfusion therapy

that were published in 2013,²⁴ “patients undergoing reperfusion with fibrinolytics should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of the index hospitalization, up to 8 days or until revascularization if performed (regimens other than UFH are recommended if anticoagulant therapy is given for more than 48 hours because of the risk of heparin-induced thrombocytopenia with prolonged UFH treatment).” An activated partial thromboplastin time (aPTT) greater than 70 seconds during treatment with UFH was shown to be associated with a higher risk of death, stroke, and bleeding among patients who were enrolled in the GUSTO-1 trial.¹⁴⁰ Therefore, the ACC/AHA guidelines recommend adjustment of the dose of UFH to maintain an aPTT of 50 to 70 seconds. Also, the platelet count should be monitored daily during treatment with UFH because there is a 3% incidence of heparin-induced thrombocytopenia.¹⁴¹ See [Box 30.3](#) for recommendations regarding the doses of UFH, enoxaparin, fondaparinux, and bivalirudin.

FIBRINOLYTIC THERAPY

The dependence of myocardial necrosis on the duration of coronary occlusion was demonstrated using a canine model of MI.¹⁴² The landmark angiographic study performed by DeWood and coworkers¹⁴³ confirmed the presence of coronary artery thrombi in patients with STEMI. Although these experimental and clinical observations provided a rationale for fibrinolytic therapy, the initial studies of fibrinolytic agents for acute MI preceded both findings. According to one review of the literature, the first reported use of fibrinolytic therapy for acute MI was in 1958.¹⁴⁴ By 1979, several multicenter studies of intravenous streptokinase had been performed, but the benefit of reperfusion therapy remained unproven, in part because the trial designs were flawed.^{145,146}

Effect of Fibrinolysis on Survival

Four well-designed, multicenter randomized trials established that three fibrinolytic agents—streptokinase,^{96,147} anisoylated plasminogen-streptokinase activator complex (APSAC) (i.e., anistreplase),¹⁴⁸ and tPA¹⁴⁹—each reduced short-term and long-term mortality in patients with acute MI. The Fibrinolytic Therapy Trialists’ Collaborative Group analyzed nine trials that randomized a total of 58,600 patients with suspected acute MI to a fibrinolytic therapy group or a control group.¹⁵⁰ The absolute risk of death increased with age, but absolute reductions in mortality were comparable among younger and older patients up to 75 years of age. Several trials had upper age limits for enrollment. The remaining trials enrolled 5788 patients 75 years or older and found no significant effect of fibrinolytic therapy on mortality at 35 days (25.3% for the control patients versus 24.3% for patients who received fibrinolytic therapy).¹⁵⁰

The baseline ECG findings and the elapsed time between the onset of symptoms and the initiation of treatment were significant determinants of the impact of fibrinolytic therapy on mortality at 35 days¹⁵⁰ ([Fig. 30.5](#)). The greatest reduction in mortality was observed in patients who presented with either bundle branch block (BBB) (control 23.6% versus fibrinolytic 18.7%) or ST segment elevation in the anterior leads (control 16.9% versus fibrinolytic

Box 30.3 Dosing of Anticoagulant Drugs for Patients with STEMI**Anticoagulation to Support Primary PCI in STEMI****Class I****Bivalirudin**

1. 0.75 mg/kg IV bolus, then 1.75 mg/kg/h infusion with or without prior treatment with UFH. Reduce infusion to 1 mg/kg/h with estimated creatinine clearance < 30 mL/min

UFH

1. With glycoprotein IIb/IIIa receptor antagonist planned: 50-70 U/kg IV bolus to achieve ACT 200-250 seconds
2. With no glycoprotein IIb/IIIa receptor antagonist planned: 70-100 U/kg IV bolus to achieve ACT 250-300 seconds

Anticoagulation in Patients Who Receive Fibrinolytic Therapy

Class I. Patients with STEMI undergoing reperfusion with fibrinolytic therapy should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of the index hospitalization, up to 8 days or until revascularization if performed (regimens other than UFH are recommended if anticoagulant therapy is given for more than 48 hours because of the risk of heparin-induced thrombocytopenia with prolonged UFH treatment). Recommended regimens include the following:

- a. UFH: initial intravenous bolus 60 U/kg (maximum 4000 U) followed by an intravenous infusion of 12 U/kg/hr (maximum 1000 U/hr) initially, adjusted to

maintain the activated partial thromboplastin time at 1.5 to 2 times control (approximately 50 to 70 seconds)

- b. Enoxaparin (provided the serum creatinine is less than 2.5 mg/dL in men and 2 mg/dL in women): for patients younger than 75 years of age, an initial 30 mg intravenous bolus, followed 15 minutes later by subcutaneous injections of 1 mg/kg every 12 hours; for patients at least 75 years of age, the initial bolus is eliminated and the subcutaneous dose is reduced to 0.75 mg/kg every 12 hours. Regardless of age, if the creatinine clearance (using the Cockcroft-Gault formula) during the course of treatment is estimated to be less than 30 mL/min, the subcutaneous regimen is 1 mg/kg every 24 hours.
- c. Fondaparinux (contraindicated if CrCl < 30 mL/min): initial dose 2.5 mg intravenously; subsequent subcutaneous injections of 2.5 mg daily starting the following day.

Anticoagulation in Patients Who Do Not Undergo Reperfusion Therapy

Class IIa. It is reasonable for patients with STEMI who do not undergo reperfusion therapy to be treated with anticoagulant therapy (non-UFH regimen) for the duration of the index hospitalization, up to 8 days.

ACT, activated clotting time; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; UFH, unfractionated heparin
 Data from Antman EM, Hand M, Armstrong PW, et al: 2007 focused update of the ACC/AHA 2004 guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing group to review new evidence and update the ACC/AHA 2004 guidelines for the management of patients with ST-elevation myocardial infarction). *J Am Coll Cardiol* 2008;51:210-247; O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guidelines for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2013;61:e78-e140.

Figure 30.5 The impact of the presenting electrocardiogram (ECG) and the time to treatment on the 35-day mortality of 58,600 patients enrolled in nine randomized trials comparing streptokinase, APSAC (anistreplase), urokinase, or tissue plasminogen activator with placebo or control, expressed as the number of lives saved per 1000 patients who received fibrinolytic therapy. Ant ST, anterior ST segment elevation; APSAC, anisoylated plasminogen-streptokinase activator complex; BBB, bundle branch block; Inf ST, inferior ST segment elevation. (From Indications for fibrinolytic therapy in suspected acute myocardial infarction: Collaborative overview of early mortality and major morbidity results from all randomised trials of more than 1000 patients. Fibrinolytic Therapy Trialists' [FTT] Collaborative Group. *Lancet* 1994;343:311-322.)

13.2%).¹⁵⁰ Fibrinolytic therapy increased mortality among patients with ST segment depression on the baseline ECG.

A linear relationship between the absolute reduction in mortality and the delay from symptom onset to randomization was found among the 45,000 patients who presented with ST elevation or BBB on the ECG.¹⁵⁰ Fibrinolytic therapy significantly reduced mortality even among patients who received treatment 7 to 12 hours after the onset of symptoms, but patients who received treatment within the first hour after the onset of their symptoms received the greatest benefit. Patients who receive fibrinolytic therapy within the first hour after symptom onset have the greatest proportional mortality reduction,¹⁵¹ as well as the highest incidence of so-called aborted MI, defined as maximal creatine kinase level up to twice the upper limit of normal and typical evolution of ECG changes.^{152,153} A multicenter trial of fibrinolytic therapy reported that the baseline-adjusted mortality was significantly lower among the 13.3% of patients who had an aborted MI than among those who did not.¹⁵²

Persistent occlusion of the IRA after acute MI is associated with left ventricular remodeling, resulting in increased left ventricular end-systolic volume, a major predictor of survival after acute MI.^{154,155} Some evidence suggests that reperfusion later than 6 hours after the onset of symptoms has a favorable effect on ventricular remodeling, with less ventricular dilation observed after successful reperfusion than after no reperfusion therapy.^{156,157} Several clinical trials have investigated the effects of fibrinolytic therapy on clinical events in patients who received treatment more than 6 hours after the onset of symptoms. A South American multicenter trial randomized 2080 patients within 7 to 12 hours after the onset of symptoms to receive streptokinase or placebo and found no significant difference in mortality rates in-hospital, after 35 days, and after 1 year.¹⁵⁸ The Late Assessment of Thrombolytic Efficacy (LATE) study randomized 5711 patients who presented with suspected acute MI between 6 and 24 hours after the onset of symptoms to receive tPA or placebo.¹⁵⁹ Treatment with tPA significantly reduced mortality among patients who received treatment within 12 hours of symptom onset: the 35-day mortality rate was 8.9% for the tPA group versus 11.97% for placebo, representing a relative reduction of 25.6% (95% CI 6.3% to 45%; $p = 0.0229$). Mortality at 35 days was not significantly reduced by the administration of tPA to patients who received treatment 12 to 24 hours after symptom onset.

The major causes of delayed fibrinolytic therapy for acute MI are failure of patients to seek medical care^{160,161} and delays in administration of fibrinolytic therapy.^{162,163} A retrospective review of data for 2409 patients hospitalized with acute MI in Minnesota in 1992 and 1993 reported that 40% of the patients delayed presentation to the hospital more than 6 hours after the onset of symptoms.¹⁶⁰ The ACC/AHA Practice Guidelines set a goal of initiating fibrinolytic therapy within 30 minutes of contact with the medical system.²⁰ Among 68,430 patients with STEMI who received fibrinolytic therapy and were enrolled in the NRMI-3 and NRMI-4 registries, only 46% of patients received a fibrinolytic drug within 30 minutes of arrival.¹⁶³ There was no significant improvement in the so-called door-to-needle time in the 1015 participating hospitals from 1999 to 2002.¹⁶³ A more recent study of 3219 patients with STEMI who received

fibrinolytic therapy in 178 hospitals between 2007 and 2008 found that the “door-to-needle” time was ≤ 30 minutes in only 44.5% of patients.¹⁶⁴ Female gender and age > 75 were associated with longer door-to-needle times.¹⁶⁴ Prehospital administration of fibrinolytic therapy has been investigated as one approach to reducing the delay between symptom onset and reperfusion.¹⁶⁵⁻¹⁶⁷ A meta-analysis of six randomized trials that compared prehospital with in-hospital fibrinolytic therapy for acute MI found that the time to fibrinolytic therapy and all-cause in-hospital mortality were significantly reduced by the prehospital administration of fibrinolytic drugs.¹⁶⁵

Coronary Artery Patency after Fibrinolytic Therapy

Early angiographic studies investigated the rates of coronary reperfusion after intracoronary¹⁶⁸⁻¹⁷⁰ or intravenous administration of fibrinolytic agents.¹⁷¹ The Thrombolysis in Myocardial Infarction (TIMI) Study Group devised a grading system of coronary patency that has been adopted widely¹⁷¹ (Box 30.4). Fibrinolysis was judged to be successful if an IRA that was occluded (TIMI grade 0 or 1) before treatment improved to either partial perfusion (TIMI grade 2) or complete perfusion (TIMI grade 3) 90 minutes after the fibrinolytic therapy began.¹⁷¹ The first TIMI trial revealed that only 31% of occluded arteries were patent (TIMI grade 2 or 3) 90 minutes after intravenous streptokinase, compared with a 62% patency rate after a 3-hour intravenous infusion of tPA ($p < 0.001$).¹⁷² Subsequent studies that examined the relationship between the TIMI grade flow and clinical outcome concluded that TIMI grade 3 flow, but not TIMI grade 2 flow, improves both in-hospital and long-term mortality after acute MI.^{173,174} Therefore, the criteria for

Box 30.4 Definitions of Perfusion in the TIMI Trial

Grade 0 (no perfusion): There is no antegrade flow beyond the point of occlusion.

Grade 1 (penetration without perfusion): The contrast material passes beyond the area of obstruction but “hangs up” and fails to opacify the entire coronary bed distal to the obstruction for the duration of the cineangiographic filming sequence.

Grade 2 (partial perfusion): The contrast material passes across the obstruction and opacifies the coronary bed distal to the obstruction. However, the rate of entry of contrast material into the vessel distal to the obstruction or its rate of clearance from the distal bed (or both) is perceptibly slower than the rate of entry into or clearance from comparable areas not perfused by the previously occluded vessel (e.g., the opposite coronary artery or the coronary bed proximal to the obstruction).

Grade 3 (complete perfusion): Antegrade flow into the bed distal to the obstruction occurs as promptly as antegrade flow into the bed proximal to the obstruction, and clearance of contrast material from the involved bed is as rapid as clearance from an uninvolved bed in the same vessel or the opposite artery.

From Thrombolysis in Myocardial Infarction (TIMI) trial: Phase I findings. TIMI Study Group. N Engl J Med 1985;312:932-936.

evaluating fibrinolytic therapy were revised, and TIMI grade 2 flow is no longer considered a successful outcome.¹⁷⁵

The GUSTO-I trial randomized 41,021 patients to four fibrinolytic strategies: streptokinase plus subcutaneous UFH, streptokinase plus intravenous UFH, accelerated tPA plus intravenous UFH, or a combination of streptokinase and tPA plus intravenous UFH.¹⁷⁶ Thirty-day mortality was lowest for the accelerated tPA-UFH regimen, 6.3%. A sub-study of GUSTO-I included 2431 patients who underwent coronary angiography to assess patency of the IRA.^{177,178} TIMI grade 3 flow was achieved 90 minutes after initiation of fibrinolytic therapy in 54% (157/292) of patients in the accelerated tPA-UFH group, compared with 31% of patients who received streptokinase plus UFH (176/576). Analysis of the relationship between patency at 90 minutes and mortality at 30 days regardless of treatment assignment revealed a significant difference between the mortality rate associated with grade 3 flow and the mortality associated with grade 0 or 1 flow (4.4% versus 8.9%; $p = 0.009$).

The relationship between time to treatment and the mortality reduction by fibrinolytic therapy may be a reflection of several factors. One is that earlier reperfusion achieves greater myocardial salvage.¹⁷⁹ Another factor is that time to treatment may influence the patency rate 90 minutes after administration of certain fibrinolytic drugs.¹⁸⁰ Patency of the IRA 90 minutes after administration of a nonfibrin-specific fibrinolytic drug, such as streptokinase, anistreplase, or urokinase, is lower when patients are first treated beyond 3 hours after the onset of symptoms than when the drugs are administered within 3 hours after onset.^{172,180-182} After treatment with tPA or reteplase (rPA), fibrin-specific fibrinolytic agents, the rates of TIMI grade 3 flow are similar for patients who received treatment within 3 hours or at 3 hours or later after the onset of symptoms.^{172,181,182} The time-dependent reperfusion efficacy is reflected by the rates of in-hospital mortality. A retrospective analysis of six angiographic trials that included 1174 patients found that in-hospital mortality among patients who received nonfibrin-specific drugs was twofold greater for patients treated more than 3 hours after symptom onset compared with patients treated within 3 hours.¹⁸² Among patients who received tPA or rPA, in-hospital mortality did not differ for patients treated within 3 hours of symptom onset or later than 3 hours after symptom onset.

More sophisticated methodologies for assessing myocardial reperfusion have been devised, such as the TIMI frame count and TIMI myocardial perfusion grade.¹⁸³⁻¹⁸⁵ Application of these methods demonstrated that even among patients with TIMI grade 3 flow after fibrinolytic therapy, clinical outcomes and survival are related to the speed of epicardial flow and the state of myocardial perfusion.^{183,184} Therefore, a major goal of research has been to determine whether combinations of fibrinolytic and antiplatelet drugs might enhance myocardial reperfusion and achieve further reductions in mortality. Compared with full-dose tPA or rPA, a combination of a reduced dose of either tPA or rPA plus abciximab, a platelet glycoprotein IIb/IIIa (GP IIb/IIIa) inhibitor, was found to increase the rates of TIMI 3 flow at 60 and 90 minutes after administration.^{186,187} Unfortunately, a difference in 30-day mortality between standard-dose rPA and half-dose rPA plus full-dose abciximab was not demonstrated by a large clinical trial, GUSTO-V, that enrolled 16,588 patients with evolving STEMI.¹⁸⁸

Complications of Fibrinolytic Therapy

Intracranial hemorrhage and other hemorrhagic complications are the major risks associated with the administration of fibrinolytic therapy.^{189,190} The NRMI-2 database accrued 71,073 patients who received tPA for acute MI from June 1, 1994, to September 30, 1996. Intracranial hemorrhage was confirmed by computed tomography (CT) or magnetic resonance imaging (MRI) in 625 patients (0.88%).¹⁹⁰ In-hospital mortality was 53%, and 25.3% of patients with intracranial hemorrhage who survived to hospital discharge had neurologic deficits. A multivariate analysis identified several risk factors that were significantly associated with an increased risk of intracranial hemorrhage: older age, female gender, systolic blood pressure greater than 140 mm Hg, diastolic blood pressure greater than 100 mm Hg, and history of stroke. An aPTT longer than 70 seconds was associated with an increased risk of hemorrhagic stroke in the GUSTO-I trial.¹²² Bolus administration of fibrinolytic agents may be associated with an increased risk of intracranial hemorrhage compared with infusion.^{191,192} Although phase II trials indicated a statistically nonsignificant reduction in the risk of intracranial hemorrhage, meta-analysis of phase III trials revealed a statistically significant 25% increase in the risk of intracranial hemorrhage with bolus fibrinolytic therapy.¹⁹² According to the ACC/AHA guidelines, "The occurrence of a change in neurological status during or after reperfusion therapy, particularly within the first 24 hours after initiation of treatment, is considered to be due to intracranial hemorrhage until proven otherwise."²⁰ When intracranial hemorrhage is suspected, an emergency CT scan should be performed, and fibrinolytic, antiplatelet, and anticoagulant therapies should be discontinued until the diagnosis is ruled out. Cryoprecipitate or fresh frozen plasma should be given to replenish coagulation factors.²⁰ Protamine should be administered to patients who are receiving UFH. Neurosurgery to evacuate parenchymal hemorrhages or subdural hematomas may improve outcome.¹⁹³

Among 40,903 patients enrolled in the GUSTO-I trial, 1.2% suffered severe bleeding, defined as bleeding that caused hemodynamic compromise that required treatment, and 11.4% experienced moderate hemorrhage, defined as bleeding that required transfusion but did not lead to hemodynamic compromise requiring intervention.¹⁸⁹ The most common sources of moderate and severe bleeding were procedure related. The rate of moderate or severe bleeding was 6% among patients who underwent no procedures, compared with 17% among patients who underwent coronary angiography, 43% among patients who received a PA catheter, and 50% among patients who received an intra-aortic balloon pump (IABP) or underwent coronary artery bypass surgery. Older age, lower body weight, and female sex were the three strongest independent predictors of hemorrhage. The risk of noncerebral bleeding was greater after streptokinase than after tPA, but the risk of intracranial hemorrhage was greater after tPA.

Patient Selection

The 2013 ACCF/AHA Guidelines for STEMI include one Class I indication for fibrinolytic therapy: in the absence of contraindications, fibrinolytic therapy should be given to patients with STEMI and onset of ischemic symptoms within

the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact.²⁴ The 2013 STEMI Guidelines also include one Class IIa recommendation for fibrinolytic therapy: in the absence of contraindications and when PCI is not available, fibrinolytic therapy is reasonable for patients with STEMI if there is clinical or ECG evidence of ongoing ischemia within 12 to 24 hours of symptom onset and a large area of myocardium at risk or hemodynamic instability.²⁴ There is a long list of absolute and relative contraindications to fibrinolytic therapy (Box 30.5). Special attention should be paid to factors that may increase the risk of intracranial hemorrhage, such as a history of such hemorrhage, recent closed head or facial trauma, uncontrolled hypertension, or ischemic stroke within the previous 3 months. PCI is

Box 30.5 Contraindications and Cautions for Fibrinolysis in ST Segment Elevation Myocardial Infarction

Absolute Contraindications

Any prior intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 months; *exception*: acute ischemic stroke within 4.5 hours
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (unresponsive to emergency therapy)
For streptokinase, prior treatment within the previous 6 months

Relative Contraindications

1. History of chronic, severe, poorly controlled hypertension
2. Severe uncontrolled hypertension on presentation (systolic blood pressure greater than 180 mm Hg or diastolic blood pressure greater than 110 mm Hg)
3. History of prior ischemic stroke more than 3 months earlier, dementia, or known intracranial pathology not covered in absolute contraindications
4. Traumatic or prolonged (beyond 10 minutes) CPR or major surgery (within 3 weeks)
5. Recent (within 2 to 4 weeks) internal bleeding
6. Noncompressible vascular punctures
7. For streptokinase/anistreplase: prior exposure (more than 5 days earlier) or prior allergic reaction to these agents
8. Pregnancy
9. Active peptic ulcer
10. Oral anticoagulant therapy

CPR, cardiopulmonary resuscitation; INR, international normalized ratio.

O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2013;61:e78-e140.

preferable to fibrinolytic therapy in patients with an increased risk of intracranial hemorrhage. Active menstrual bleeding should not be considered a contraindication to fibrinolytic therapy.^{194,195} The GUSTO-I trial included 12 menstruating women who received fibrinolytic therapy, 2 of whom required a transfusion for moderate vaginal bleeding.¹⁹⁵ Nontraumatic cardiopulmonary resuscitation also should not be considered a contraindication to fibrinolytic therapy.^{194,196}

Increasing age is a risk factor for death and other adverse events after either primary PCI or fibrinolytic therapy for STEMI.¹⁹⁷ The risk of intracranial hemorrhage after fibrinolytic therapy also increases with advancing age.^{190,198} Data are conflicting regarding the benefit or lack of benefit of fibrinolytic therapy in patients with STEMI who are older than 75. One analysis of a Medicare database that included 2673 patients aged 76 to 86 found that fibrinolytic therapy conferred a survival disadvantage, with a hazard ratio of 1.38 for 30-day mortality.¹⁹⁹ Fibrinolytic therapy was associated with a 13% reduction in the composite of 1-year mortality and cerebral bleeding in a cohort of 6891 patients 75 years and older with a first STEMI who were enrolled in a Swedish registry.²⁰⁰ A study performed in the Netherlands randomized 87 patients with acute MI who were older than 75 to primary PCI or streptokinase.²⁰¹ The primary composite end point of death, reinfarction, or stroke at 30 days occurred in 4 (9%) patients in the PCI group, compared with 12 (29%) in the streptokinase group (RR 4.3, 95% CI 1.2 to 20; $p = 0.01$). After 1 year, mortality was significantly greater for the streptokinase group than for the PCI group (29% versus 11%; RR 3.4, 95% CI 1.0 to 13.5; $p = 0.03$). One caveat regarding the study is that the mean time from hospital admission to first balloon inflation was 59 ± 19 minutes (range 33 to 120 minutes)—considerably shorter than door-to-balloon times in the United States.

Many patients with acute MI have contraindications to fibrinolytic therapy or do not meet eligibility criteria for fibrinolytic therapy.^{202,203} Contraindications such as recent surgery, trauma, or gastrointestinal bleeding would be relatively frequent in patients who develop an acute MI while already hospitalized for another illness. Analysis of patients with STEMI who were enrolled in the NRM-2, -3, and -4 databases suggested that immediate mechanical reperfusion using either PCI or coronary artery bypass surgery reduced the risk of in-hospital death among patients with contraindications to fibrinolytic therapy.²⁰⁴

PERCUTANEOUS CORONARY INTERVENTION

Dr. Andreas Gruntzig performed the first balloon angioplasty of a coronary artery in 1977.²⁰⁵ Dr. Peter Rentrop reported his initial experience with PCI for acute MI in 1979.^{206,207} O'Neill and colleagues²⁰⁸ published a randomized trial of PCI compared with intracoronary streptokinase for acute MI in 1986. The most recent meta-analysis identified 23 trials that randomly assigned a total of 7739 patients with STEMI to receive intravenous fibrinolytic therapy or undergo primary PCI, defined as PCI without previous or concomitant fibrinolytic therapy.²⁰⁹ Numerous other randomized trials have been performed to investigate several other applications of PCI in patients with acute MI. Rescue PCI refers to PCI that is performed after unsuccessful fibrinolytic therapy. After successful fibrinolysis, PCI may be

performed immediately, on a routine, deferred basis, or in a selective fashion (e.g., to treat inducible ischemia).

Primary Percutaneous Intervention

Myocardial salvage and long-term mortality are correlated with both the TIMI grade flow and the myocardial blush grade achieved after primary PCI for STEMI.²¹⁰⁻²¹³ TIMI grade 3 flow is achieved in a high percentage of patients who undergo primary PCI for STEMI. The largest clinical trial of PCI compared with fibrinolytic therapy for acute MI was the Danish Multicenter Randomized Study on Fibrinolytic Therapy versus Acute Coronary Angioplasty in Acute Myocardial Infarction (DANAMI-2) study.²¹⁴⁻²¹⁶ Immediate angiography was performed in 777 of the 790 (98%) patients who were randomized to undergo PCI. The initial angiogram showed TIMI grade 0 or 1 flow in 68% of patients, and grade 3 flow in 18%. PCI was attempted in 706 patients, resulting in postprocedural flow of TIMI grade 3 in 82%, grade 2 in 16%, and grade 0 or 1 in 2%. The Zwolle Myocardial Infarction Study Group reported the outcome of 1702 patients who underwent PCI for STEMI.²¹⁷ Successful PCI, defined as TIMI grade 3 flow and a residual lumen diameter less than 50%, was achieved more often during routine hours (8 a.m. to 6 p.m.) than during off-hours (6 p.m. to 8 a.m.) (96.2% versus 93.1%; $p < 0.01$).

Despite the presence of TIMI grade 3 flow, the myocardial blush grade, an indicator of myocardial perfusion, is abnormal in a majority of patients who undergo primary PCI for STEMI.^{211,212} Among a cohort of 777 patients who underwent primary PCI for STEMI, normal myocardial blush (grade 3) was achieved in only 148 patients (19%), whereas 236 patients (30%) had blush grade 0 or 1.²¹¹ Multivariate analysis showed that myocardial blush grade was an independent predictor of long-term mortality, with mortality after follow-up for 1.9 ± 1.7 years of 3% for grade 3, 6% for grade 2, and 23% for grade 0 or 1 myocardial blush ($p < 0.0001$).²¹¹

Distal embolization of thrombus²¹⁸ and microvascular “no reflow”²¹⁹ are two of the mechanisms of impaired myocardial perfusion after primary PCI. Distal embolization was observed in 27 of 178 patients (15%) who underwent primary PCI for STEMI.²¹⁸ Patients with distal embolization had lower left ventricular EFs at discharge from the hospital and higher long-term mortality. Microvascular obstruction detected by MRI is a prognostic marker for cardiovascular events after acute MI, even after controlling for infarct size.²¹⁹ Numerous clinical trials have been performed to investigate various mechanical methods of protecting the coronary microcirculation during PCI for ACS or acute STEMI.²²⁰⁻²³¹ Two different distal embolic protection devices, one that consists of a distal balloon occlusion and aspiration system and another that employs a filter, failed to improve myocardial reperfusion, reduce infarct size, or improve event-free survival in patients with acute MI.²²⁴⁻²²⁶ A meta-analysis of 12 clinical studies concluded that the distal embolic protection devices had no significant effect on mortality.²²⁹

Use of the X-Sizer thrombectomy catheter (ev3, Inc., Plymouth, Minnesota) before coronary angioplasty or stenting appears to reduce distal embolization and improve epicardial flow, myocardial blush, and resolution of ST segment elevation, especially in patients with angiographic evidence

of intraluminal thrombus.²²⁰⁻²²² The AngioJet Rheolytic Thrombectomy catheter (Possis Medical, Inc., Minneapolis, Minnesota) was evaluated in a multicenter, randomized study called the AngioJet Rheolytic Thrombectomy in Patients Undergoing Primary Angioplasty for Acute Myocardial Infarction (AIMI) study.²²³ The AIMI trial randomized 480 patients within 12 hours of symptom onset of STEMI to PCI alone or PCI with adjunctive rheolytic thrombectomy. No significant differences were observed in myocardial perfusion blush or resolution of ST segment elevation. Infarct size measured by myocardial perfusion imaging was greater in the thrombectomy group, and major adverse cardiac events were more frequent in the thrombectomy group (6.7% versus 1.7%; $p = 0.01$).²²³ A meta-analysis of five randomized trials concluded that adjunctive mechanical thrombectomy with either the AngioJet catheter or the X-Sizer catheter was associated with increased mortality compared with PCI alone (5.3% versus 2.8%; $p = 0.05$) in patient with acute MI.²²⁹

At least 16 clinical trials have been performed to test the effect of aspiration thrombectomy on clinical outcomes in patients with STEMI. The largest trial, the Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction Study (TAPAS), was an open trial with a blinded evaluation of end points that randomized 1071 patients to either conventional PCI or thrombus aspiration using a 6 French aspiration catheter during PCI.^{227,228} Thrombus aspiration resulted in improved myocardial blush grade and resolution of ST-segment elevation, and lower 1-year mortality.^{227,228} Three of the four meta-analyses of randomized trials have concluded that adjunctive manual aspiration thrombectomy improves mortality in patients undergoing primary PCI for STEMI.²²⁹⁻²³² The 2009 Focused Updates of the ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction included a Class IIa recommendation for aspiration thrombectomy during PCI for STEMI.²²

Abciximab, a GP IIb/IIIa inhibitor, has been reported to improve recovery of microvascular perfusion after PCI for acute MI.²³³ An intracoronary bolus of abciximab reduced infarct size at 30 days by a small but significant amount in patients who underwent primary PCI for STEMI due to occlusion of the proximal or middle segments of the left anterior descending coronary artery.²³⁴ On the basis of observations from small studies, intracoronary vasodilators, such as adenosine, frequently are employed to treat “no reflow” after PCI.²³⁵⁻²³⁷

Proponents of primary PCI and fibrinolytic therapy for acute MI have written excellent reviews of the advantages and disadvantages of both reperfusion therapies.^{238,239} The evidence base supporting primary PCI for STEMI includes single-center series, multicenter randomized trials, large registries, and several meta-analyses. The Myocardial Infarction Triage and Intervention (MITI) Project Registry described a cohort of patients with acute MI who either underwent primary angioplasty (1050 patients) or received fibrinolytic therapy (2095 patients) at 19 hospitals in Seattle, Washington, between 1988 and 1994.²⁴⁰ No significant difference in mortality was observed during hospitalization or long-term follow-up between the two groups. The MITI Registry included patients who received streptokinase, whereas a subsequent NRMI-2 report that was limited to patients who

received tPA also found that in-hospital outcomes were similar for both methods of reperfusion.²⁴¹ Another cohort study of 20,683 Medicare beneficiaries with acute MI concluded that 30-day and 1-year mortality rates were lower among patients who underwent primary angioplasty than among patients who received fibrinolytic therapy.²⁴²

The DANAMI-2 trial did not show a significant difference between PCI and fibrinolytic therapy in the rates of death or stroke at 30 days, but the rate of reinfarction at 30 days was significantly lower: 1.6% for the PCI group compared with 6.3% for the fibrinolysis group ($p < 0.001$).²¹⁴ Although the 3-year mortality was not significantly different among low-risk patients, defined as a TIMI score of 0 to 4, the 3-year mortality among high-risk patients, defined as a TIMI score ≥ 5 , was significantly lower for the patients who underwent PCI compared with the patients who received fibrinolytic therapy.²¹⁵ Published meta-analyses of PCI versus fibrinolytic therapy included DANAMI-2 and 22 other randomized trials.^{209,243} The trials were rather heterogeneous in design: stents were used in 12 trials, GP IIb/IIIa inhibitors were used in 8 trials, and 5 trials compared fibrinolytic therapy with PCI performed after transfer from a referral hospital to a hospital that provides invasive cardiac services. The rates of short-term death, nonfatal reinfarction, stroke, and the combined end point of death, nonfatal reinfarction, and stroke were lower for PCI than fibrinolytic therapy. Another analysis pooled the individual patient 6-month follow-up data from 11 randomized trials of PCI versus fibrinolytic therapy for acute MI.²⁴⁴ At 6 months, the mortality rates were 6.2% for PCI and 8.2% for fibrinolysis (RR 0.73; CI 0.55 to 0.98; $p = 0.04$). A meta-analysis of 11 randomized trials that enrolled 4320 patients with STEMI found that long-term mortality (≥ 1 year) was 24% lower among patients treated with primary PCI compared with patients treated with fibrinolytic therapy.²⁴³ A meta-analysis of 12 observational studies that enrolled 54,571 patients with STEMI found that long-term mortality was not significantly reduced by primary PCI compared with fibrinolytic therapy.²⁴³

Analysis of patients enrolled in NRMI-2 showed that the in-hospital mortality was 28% lower among patients who underwent primary PCI at hospitals with the highest volume than among those who had PCI at hospitals with the lowest volume (adjusted RR 0.72; CI 0.60 to 0.87; $p < 0.001$).²⁴⁵ Among 463 hospitals that performed primary PCI for STEMI and participated in NRMI-4, the hospitals with the greatest relative utilization of primary PCI, versus fibrinolytic therapy, for reperfusion had shorter door-to-balloon times and lower in-hospital mortality rates.²⁴⁶ These data may have provided some of the rationale for the ACC/AHA Practice Guidelines regarding the performance of PCI for STEMI.²⁰ PCI should be performed in a cardiac catheterization laboratory that performs more than 200 PCI procedures per year, including at least 36 cases of primary PCI for STEMI. The operator should perform more than 75 PCI procedures per year.

Both the extent of myocardial salvage^{179,247} and the mortality benefit^{150,248,249} of fibrinolytic therapy and primary PCI are inversely related to the time elapsed between symptom onset and treatment. Among a cohort of 1791 patients with STEMI treated with primary PCI, the relative risk (RR) of death at 1 year increased by 7.5% for each 30-minute delay.²⁵⁰ Several studies have analyzed the relationship

between mortality and the so-called door-to-balloon time, defined as the duration of time between arrival at the hospital and the first balloon inflation.^{249,251-253} Although some studies found that in-hospital mortality was not related to the door-to-balloon time,²⁵¹ most studies have shown that both in-hospital and late mortality are higher when door-to-balloon time is longer.^{249,252,253} Among 2082 patients with acute MI who were enrolled in the CADILLAC trial, door-to-balloon time was an independent predictor of 1-year mortality in patients who presented within 2 hours after the onset of symptoms ($n = 965$; hazard ratio 1.24; 95% CI 1.05 to 1.46; $p = 0.013$), but not in patients who presented later than 2 hours ($n = 944$; hazard ratio 0.88; 95% CI 0.67 to 1.15; $p = 0.33$).²⁵⁴

The ACC/AHA Practice Guidelines set a goal of balloon inflation within 90 minutes of presentation, but observational studies indicate that this goal is seldom achieved.^{163,255} Among 33,647 patients with STEMI who underwent primary PCI between 1999 and 2002 and were enrolled in the NRMI-3 and NRMI-4 registries, only 35% of patients received treatment within 90 minutes of arrival.¹⁶³ Krumholz and colleagues²⁵⁶ analyzed the door-to-balloon times reported by hospitals to the Centers for Medicare & Medicaid Services from January 1, 2005, through September 30, 2010. Door-to-balloon time decreased from a median of 96 minutes in 2005 to a median of 64 minutes during the first three quarters of 2010.²⁵⁶ The percentage of patients who had door-to-balloon times < 90 minutes increased from 44.2% to 91.4%.²⁵⁶

The time of day and day of week had significant effects on door-to-balloon times among 33,647 patients with STEMI who underwent primary PCI between 1999 and 2002 and were enrolled in the NRMI-3 and NRMI-4 registries.²⁵⁷ Fifty-four percent of patients who underwent primary PCI were treated during off-hours (weekdays, 5 p.m. to 7 a.m. and weekends). Door-to-balloon times exceeded 90 minutes in 74% of patients who underwent PCI during off-hours, compared with 53% of patients treated during regular hours (weekdays, 7 a.m. to 5 p.m.) ($p < 0.001$). Treatment delays are far greater among patients who are transferred to another hospital to undergo primary PCI.²⁵⁵ Among 4278 patients who underwent interhospital transfer for primary PCI during the period 1999 to 2002, the median total door-to-balloon time was 180 minutes.²⁵⁵ Only 4.2% of patients underwent PCI within the benchmark of 90 minutes.²⁵⁵ Analysis of 23 randomized trials that compared primary PCI with fibrinolytic therapy for STEMI indicated that PCI affords a mortality advantage only if the door-to-balloon time exceeds the door-to-needle time by less than 1 hour.²⁵⁸

Several approaches have been suggested to reduce the delay between symptom onset and reperfusion in patients treated by primary PCI. One approach that has been tested is performance of primary PCI at hospitals that have cardiac catheterization laboratories but lack on-site cardiac surgery.^{259,260} One trial randomized patients with STEMI to undergo primary PCI ($n = 225$) or receive accelerated tPA ($n = 226$) at 11 community hospitals without on-site cardiac surgery.²⁶⁰ The composite end point of death, recurrent MI, and stroke was significantly lower among patients treated with primary PCI than among those who received tPA, both 6 weeks after MI (10.7% versus 17.7%; $p = 0.03$) and 6 months after MI (12.4% versus 19.9%; $p = 0.03$). A

subsequent study by the NRMIs investigators compared the outcomes of 58,821 patients with STEMI who presented to 214 hospitals with on-site cardiac surgery with the outcomes of patients who presented to 52 hospitals without on-site cardiac surgery.²⁶¹ The patients who presented to hospitals without on-site cardiac surgery were less likely to receive guideline-recommended medications within 24 hours, and they were less likely to undergo acute reperfusion therapy, but there was no difference in mortality among patients who underwent primary PCI.²⁶¹ A meta-analysis of 11 studies that included 124,074 patients who underwent primary PCI for STEMI found that the in-hospital mortality for patients at hospitals without on-site cardiac surgery was not different from hospitals having on-site surgery (odds ratio, 0.96; 95% CI 0.88 to 1.05).²⁶² Another proposed strategy to reduce the delay between symptom onset and reperfusion is the diversion of patients with acute MI to a primary PCI hospital, instead of the current practice of transporting patients to the nearest emergency department.²³⁸ A survey of 365 hospitals identified six strategies that were significantly associated with a faster door-to-balloon time.²⁶³ The use of prehospital ECGs to diagnose and triage patients with a suspected STEMI is associated with a greater use of reperfusion therapy and shorter door-to-needle and door-to-balloon times.²⁶⁴

Late reocclusion after successful primary angioplasty is associated with decreased long-term survival.²⁶⁵ The CADILLAC trial randomized 2082 patients with acute MI to undergo percutaneous transluminal coronary angioplasty (PTCA) or stenting.²⁶⁶ Although stenting did not improve the myocardial blush score,²⁶⁷ the angiographic rates of reocclusion of the IRA at 7 months was 5.7% after coronary stenting, compared with 11.3% after PTCA.²⁶⁶

At least 15 randomized clinical trials and at least 5 observational studies, plus numerous meta-analyses of those studies, have been performed to compare drug-eluting stents (DES) with bare metal stents (BMS) in patients with STEMI. The largest randomized trial enrolled 3006 patients with STEMI and found that compared with BMS, paclitaxel-eluting stents reduced angiographic evidence of restenosis and repeat revascularization for recurrent ischemia, without increasing the risk of stent thrombosis or death at 12 months.²⁶⁸ Among 7217 patients who underwent PCI with stenting for acute MI in Massachusetts between April 1, 2003, and September 30, 2004, treatment with DES, compared with BMS, was associated with decreased rates of 2-year mortality and need for repeat revascularization.²⁶⁹ On the other hand, the multinational GRACE registry reported that mortality from either 6 months to 2 years or from 1 to 2 years was significantly greater among 5093 STEMI patients who received DES, compared with BMS.²⁷⁰ A meta-analysis of five observational studies found that STEMI patients treated with DES had a significantly lower mortality compared with patients who received BMS (odds ratio 0.65; 95% CI 0.53 to 0.80; $p < 0.001$).²⁷¹ A meta-analysis of 15 randomized, controlled trials that enrolled a total of 7867 STEMI patients concluded that compared with a BMS, a DES was associated with a reduction in target vessel revascularization, but an increased risk of very late stent thrombosis (> 1 year after PCI).²⁷² The apparent increased risk of very late stent thrombosis is consistent with both post-mortem and in vivo evidence of higher rates of incomplete stent apposition and

uncovered stent struts among STEMI patients treated with DES compared with BMS.^{273,274} Nevertheless, the 2009 Focused Updates of the ACC/AHA STEMI and PCI guidelines include a Class IIa recommendation that “It is reasonable to use a DES as an alternative to a BMS for primary PCI in STEMI.”²²

Rescue Percutaneous Coronary Intervention

Compared with TIMI grade 3 flow, TIMI grade 0 or 1 flow at 90 minutes after fibrinolytic therapy is associated with worse left ventricular function and increased mortality rates.^{177,178} Compared with complete resolution of ST segment elevation, incomplete resolution of ST segment elevation after fibrinolytic therapy is associated with larger infarct size and greater short-term and long-term mortality.^{42,44,275} Therefore, various angiographic or electrocardiographic criteria have been employed to define unsuccessful fibrinolysis and rescue PCI. A report from the TIMI 10B and TIMI 14 trials of fibrinolytic therapy defined rescue PCI as PCI performed between 90 and 150 minutes after the start of therapy for patients with TIMI 0 or 1 flow 90 minutes after the start of therapy.²⁷⁶ The Middlesbrough Early Revascularization to Limit Infarction (MERLIN) trial defined failed fibrinolytic therapy as failure of the ST segment elevation in the worst lead to have resolved by 50% 60 minutes after the onset of fibrinolytic therapy.²⁷⁷ The Rescue Angioplasty versus Conservative Treatment or Repeat Thrombolysis (REACT) trial's definition of rescue PCI was PCI performed within 12 hours after failed fibrinolytic therapy, defined as an ECG obtained 90 minutes after the start of fibrinolytic therapy that showed $< 50\%$ resolution of the ST segment in the lead showing the greatest ST segment elevation.²⁷⁸ Thus, many of the patients who underwent PCI in the REACT trial would meet the TIMI group's definition of either adjunctive PCI, defined as PCI for patients with TIMI grade 2 or 3 flow, or delayed PCI, defined as PCI longer than 150 minutes after fibrinolytic therapy, rather than rescue PCI as defined by the TIMI group and other investigators.²⁷⁶ Among patients enrolled in the TIMI 10B and 14 trials, the rate of TIMI grade 3 flow was significantly greater after adjunctive PCI than after rescue PCI (89% versus 78%, $p = 0.001$),²⁷⁶ which might account for the REACT trial's 98% (106 of 108 patients) success rate for rescue PCI.²⁷⁸

There is conflicting information regarding the impact of rescue PCI on mortality. Among 150 patients who were enrolled in the TIMI 10B trial and had TIMI 0 or 1 flow 90 minutes after fibrinolytic therapy, 2-year mortality was significantly less among the patients who underwent rescue PCI ($n = 120$) than among those who did not ($n = 30$) ($p = 0.03$).²⁷⁹ The randomized trials that compared rescue PCI with conservative therapy were insufficiently powered to detect an effect on mortality. Although differences in trial design and the definition of rescue PCI make it somewhat difficult to compare the results of various trials, at least two meta-analyses of the randomized trials have been published.^{280,281} A pooled analysis of the short-term mortality (in-hospital or 30-day) among 942 patients who were enrolled in five randomized trials revealed that the risk of death was 36% lower among patients who were randomized to PCI (RR 0.64, 95% CI 0.41 to 1.00, $p = 0.048$).²⁸⁰ Another meta-analysis included six trials that randomized 908 patients to rescue PCI or conservative therapy.²⁸¹ Rescue PCI

was not associated with a reduction in all-cause mortality at 6 months (RR 0.69; 95% CI 0.46 to 0.105), but it was associated with significant reductions in the risk of heart failure and reinfarction, and an increased risk of stroke and minor bleeding.²⁸¹

Perhaps as a result of the varying definitions used to define rescue PCI, the term *rescue PCI* was not employed in the 2009 Focused Updates of the STEMI and PCI practice guidelines.²² Based on the results of the TRANSFER-AMI study, the guidelines recommend that high-risk STEMI patients who receive fibrinolytic therapy at a non-PCI-capable facility should be transferred immediately to a PCI-capable facility for diagnostic cardiac catheterization and PCI if appropriate. High-risk patients are defined as ≥ 2 mm of ST segment elevation in two anterior leads, or ≥ 1 mm of ST segment elevation in inferior leads with at least one of the following: systolic blood pressure < 100 mm Hg, heart rate > 100 /min, Killip class II or III, ≥ 2 mm of ST segment depression in the anterior leads, or ≥ 1 mm of ST segment elevation in right-sided lead V4 indicative of right ventricular involvement.²²

SELECTION OF REPERFUSION STRATEGY

There is evidence that reperfusion therapy is underutilized in the United States.²⁸² The NRMI-2 registry included 84,663 patients with STEMI who presented to the hospital with diagnostic ECG changes on the initial ECG within 6 hours after symptom onset, and without contraindications to fibrinolytic therapy.²⁸² Despite their eligibility to receive reperfusion therapy, 24% received none (i.e., neither fibrinolytic therapy nor PCI). Age older than 75 years, female gender, lack of chest pain at presentation, and LBBB were independent predictors of failure to receive reperfusion therapy. Among patients enrolled in the NRMI-2 registry, patients in Killip class II or III were less likely to receive reperfusion therapy than patients in Killip class I.²⁸³

Patients who are candidates for reperfusion therapy and present initially to a PCI-capable facility should undergo cardiac catheterization with an intention of performing PCI within 90 minutes of arrival. Patients who are candidates for reperfusion therapy and present initially to a non-PCI-capable facility may be treated with fibrinolytic therapy or transferred to a PCI-capable facility for primary PCI. Transfer to a PCI-capable facility is favored for patients who have a high bleeding risk from fibrinolytic therapy, patients who present more than 4 hours after the onset of symptoms, and patients who present with high-risk features (≥ 2 mm of ST segment elevation in 2 anterior leads or ≥ 1 mm ST segment elevation in inferior leads with at least one of the following: systolic blood pressure < 100 mm Hg, heart rate > 100 /min, Killip class II or III, ≥ 2 mm of ST segment depression in the anterior leads, or ≥ 1 mm of ST segment elevation in right-sided lead V4 indicative of right ventricular involvement).

Analysis of the NRMI-2 registry suggested that the risk of in-hospital death was reduced more by primary PCI than by fibrinolytic therapy in patients with CHF.²⁸³ Thus, the ACC/AHA Practice Guidelines recommend primary PCI for patients with severe CHF or pulmonary edema (Killip class III) when the onset of symptoms is within 12 hours.²⁰ Primary PCI is considered reasonable (a Class IIa recommendation) for patients who present with severe CHF, persistent ischemic symptoms, or hemodynamic or electrical instability 12

to 24 hours after symptom onset.²⁰ As discussed subsequently, cardiogenic shock within 36 hours of acute MI is considered an indication for primary PCI.

PCI may be preferable to fibrinolytic therapy in patients with acute MI who are classified as high risk by virtue of a TIMI risk score of 5 or higher.²¹⁵ Among 1527 patients who were enrolled in the DANAMI-2 trial, no difference in mortality was observed between low-risk patients (TIMI score 0 to 4) who underwent primary PCI and those who received fibrinolytic therapy (8% versus 5.6%; $p = 0.11$) (Fig. 30.6).²¹⁵ The 3-year mortality rate was significantly lower in high-risk patients who underwent PCI than in patients who received fibrinolytic therapy (25.3% versus 36.2%; $p = 0.02$) (see Fig. 30.6).²¹⁵

Acute MI in patients who have undergone previous CABG surgery frequently is due to thrombotic occlusion of saphenous vein bypass grafts, rather than occlusion of native coronary arteries.^{284,285} Data are limited regarding the efficacy of intravenous fibrinolytic therapy in patients with previous CABG surgery, but in one small study, angiography revealed extensive residual thrombus in the presumed culprit vein grafts.²⁸⁴ The Second Primary Angioplasty in Myocardial Infarction Trial (PAMI-2) included 58 patients with previous surgery who had either STEMI or NSTEMI.²⁸⁵ The infarct-related vessel was a native coronary artery in 26 patients (45%) and a bypass graft in 32 patients (55%), including 31 saphenous vein grafts and 1 internal mammary artery graft. PCI was attempted in 72% of the bypass grafts, resulting in TIMI grade 3 flow in only 70.2% of the grafts, compared with 94.3% of native coronary arteries in patients without previous CABG surgery.

Patients presenting more than 12 hours after symptom onset are not considered candidates for fibrinolytic therapy but may benefit from primary PCI.²⁸⁶ A trial that compared primary PCI with conservative therapy included 365 patients with acute STEMI between 12 and 48 hours after symptom onset.²⁸⁶ Left ventricular infarct size measured by technetium Tc 99m sestamibi imaging 5 to 10 days after randomization was significantly smaller in patients managed using invasive strategies than in patients managed conservatively (8% versus 13%; $p < 0.001$). The Occluded Artery Trial (OAT) randomized 2166 stable patients with one- or two-vessel CAD and a total occlusion of the IRA 3 to 28 days after MI to medical therapy or PCI with stenting.²⁸⁷ PCI did not reduce the occurrence of death, reinfarction, or CHF. Consequently, the following new Class III recommendation was included in the 2007 Focused Update of the ACC/AHA 2004 Guidelines for the Management of Patients with STEMI: "PCI of a totally occluded infarct artery greater than 24 hours after STEMI is not recommended in asymptomatic patients with one- or two-vessel disease if they are hemodynamically and electrically stable and do not have evidence of severe ischemia."²¹

PLATELET GLYCOPROTEIN IIb/IIIa RECEPTOR ANTAGONISTS

Numerous clinical trials have investigated the role of platelet GP IIb/IIIa inhibitors in patients with acute STEMI, either in conjunction with fibrinolytic agents or primary PCI.^{288,289} One rationale of including a GP IIb/IIIa inhibitor in either pharmacologic or mechanical reperfusion strategies is that platelet inhibition may improve

Figure 30.6 Mortality rates for low-risk patients (dashed lines) and high-risk patients (solid lines) who were randomized to receive fibrinolysis (Fx) (blue lines) or primary angioplasty (PA) (red lines) in the DANAMI-2 trial. Among 1134 patients who were classified as low risk by virtue of a TIMI risk score of 0 to 4, mortality after fibrinolysis and primary angioplasty was not significantly different. Among 393 patients with a TIMI risk score of 5 or higher, mortality was significantly lower after primary angioplasty compared with fibrinolysis. DANAMI, Danish Multicenter Randomized Study on Fibrinolytic Therapy versus Acute Coronary Angioplasty for Acute Myocardial Infarction; Fx, fibrinolytic therapy; PA, primary angioplasty; PTCA, percutaneous transluminal coronary angioplasty; TIMI, Thrombolysis in Myocardial Infarction study. (From Thune JJ, Hoefsten DE, Lindholm MG, et al: Simple risk stratification at admission to identify patients with reduced mortality from primary angioplasty. *Circulation* 2005;112:2017-2021.)

myocardial perfusion and enhance salvage of ischemic muscle by reducing distal embolization of platelet aggregates. Another proposed rationale is to achieve coronary artery patency using lower doses of fibrinolytic drugs. Although the addition of abciximab to either tPA²⁹⁰ or rPA¹⁸⁷ has been shown to improve angiographic indices of myocardial reperfusion, combination therapy with abciximab and a fibrinolytic drug has not been shown to reduce mortality compared with fibrinolytic therapy alone. A trial that randomized 16,588 patients with acute STEMI to treatment with either standard-dose rPA or half-dose rPA plus full-dose abciximab showed no differences in either 30-day or 1-year mortality.²⁹¹ A meta-analysis of three fibrinolytic trials that included 23,166 patients who were randomized to receive either abciximab plus half-dose rPA or tenecteplase (TNK) versus full-dose rPA or TNK found that abciximab was associated with a significant reduction in the 30-day rate of reinfarction (2.3% versus 3.6%; $p < 0.001$), but 30-day mortality was 5.8% for both groups.²⁸⁸ Therefore, there is no Class I indication for a combination of fibrinolytic agents with GP IIb/IIIa inhibitors in the ACC/AHA Practice Guidelines.²⁰

Although at least 18 randomized trials have been performed to evaluate GP IIb/IIIa inhibitors in patients with acute STEMI who undergo primary PCI, it has been difficult to draw definitive conclusions for several reasons.²⁸⁹ First, three different GP IIb/IIIa inhibitors have been studied, abciximab and the so-called small molecule inhibitors eptifibatide and tirofiban. Second, the agents have been studied in conjunction with various other antiplatelet, anticoagulant, and fibrinolytic regimens. Third, the timing of drug administration has varied from prehospital therapy to periprocedural treatment. Fourth, the trials have been underpowered to evaluate the effects on mortality.

The largest trial, HORIZONS-AMI, compared the combination of UFH and a GP IIb/IIIa inhibitor, either abciximab

or eptifibatide, with bivalirudin in 3602 patients with STEMI who were treated with primary PCI.¹³⁷⁻¹³⁹ Compared with UFH plus a GP IIb/IIIa inhibitor, treatment with bivalirudin was associated with a reduced rate of major bleeding and, among patients who were classified as “high risk,” a lower 1-year mortality rate.^{138,139}

A meta-analysis of 16 trials that enrolled a total of 10,085 patients with STEMI who underwent primary PCI concluded that GP IIb/IIIa inhibitors did not reduce the rates of mortality or reinfarction at 30 days.²⁸⁹ A meta-analysis of 5 randomized trials ($n = 2138$ patients) that compared abciximab with the small-molecule GP IIb/IIIa inhibitors in STEMI patients undergoing primary PCI found no differences in outcome.²⁹² A meta-analysis that included 1662 patients who were enrolled in 11 randomized trials that compared early versus late administration of GP IIb/IIIa inhibitors before primary PCI concluded that early administration of abciximab improved survival compared with late administration.²⁹³ A registry that enrolled 1086 patients who received abciximab also found that early administration of abciximab before transfer for PCI, compared with late administration, was associated with lower 1-year mortality among patients with a TIMI risk score ≥ 3 .²⁹⁴ A meta-analysis of 8 randomized trials that compared intracoronary with intravenous administration of GP IIb/IIIa inhibitors during primary PCI for STEMI found that intracoronary administration was associated with improved post-PCI blood flow and reduced mortality at 30 days.²⁹⁵ The INFUSE-AMI trial, however, compared the effects of intracoronary abciximab with no abciximab in patients undergoing primary PCI for an anterior STEMI, and there was no significant difference in infarct size at 30 days measured by MRI.²³⁴

Based on these data, the 2009 focused update of the ACC/AHA Guidelines for the Management of Patients with STEMI included no Class I recommendations and two Class

II recommendations regarding the use of GP IIb/IIIa receptor antagonists in patients with STEMI.²² A Class IIa recommendation is “It is reasonable to start treatment with glycoprotein IIb/IIIa receptor antagonists at the time of primary PCI (with or without stenting) in selected patients with STEMI.” A Class IIb recommendation is “The usefulness of glycoprotein IIb/IIIa receptor antagonists (as part of a preparatory pharmacological strategy for patients with STEMI before their arrival in the cardiac catheterization laboratory for angiography and PCI) is uncertain.”

β-BLOCKERS

β-Adrenergic blockers exert both antiarrhythmic and anti-ischemic effects. Experimental studies have shown that β-blockers increase the ventricular fibrillation threshold in ischemic myocardium,²⁹⁶ and randomized clinical trials have demonstrated that early administration of intravenous followed by oral metoprolol reduces the incidence of ventricular fibrillation in patients with acute STEMI.^{297,298}

Experimental studies have shown that β-blockers can limit the extent of myocardial infarction during coronary occlusion because they reduce heart rate, systemic arterial pressure, and myocardial contractility, thereby decreasing myocardial oxygen demand. Clinical data are conflicting, however, regarding the effects of β-blockers on infarct size in patients, with several studies showing reduced infarct size^{299,300} and at least one showing no reduction.³⁰¹

Numerous clinical trials have been performed to examine the effects of early or delayed β-blockade on short-term and long-term clinical outcomes in patients with acute MI. Both atenolol³⁰² and metoprolol³⁰³ administered by intravenous infusion followed by oral administration reduced mortality in patients who did not receive fibrinolytic therapy. A pooled analysis of 27 randomized trials indicated that early β-blockade reduced mortality by 13% in the first week, and the mortality reduction benefit was greatest in the first 2 days.³⁰⁴

Subsequent trials have examined the impact of early intravenous β-blockade on the outcome of patients treated with fibrinolytic agents for acute STEMI.^{305,306} In the TIMI II-B study, 1434 patients who received intravenous tPA for acute STEMI were randomized to immediate or deferred β-blockade.³⁰⁵ The deferred blockade group received oral metoprolol beginning on day 6, whereas the immediate blockade group received intravenous metoprolol within 2 hours of initiation of tPA, followed by oral metoprolol. The incidence of reinfarction (2.7% versus 5.1%, $p = 0.02$) and recurrent chest pain (18.8% versus 24.1%, $p < 0.02$) at 6 days was lower in the immediate group. The GUSTO-I trial protocol recommended that patients without hypotension, bradycardia, or heart failure receive intravenous atenolol as soon as possible after enrollment, followed by oral atenolol daily.³⁰⁶ Although adjusted 30-day mortality was significantly lower in patients who received atenolol, intravenous atenolol was associated with greater mortality compared with oral treatment alone (odds ratio 1.3; 95% CI 1.0 to 1.5; $p = 0.02$). Also, administration of intravenous atenolol was associated with increased risks of heart failure, shock, recurrent ischemia, and need for a pacemaker. The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) randomized patients with suspected acute MI to treatment with metoprolol (up to 15 mg intravenously, followed by 200 mg/day

orally; $n = 22,929$) or placebo ($n = 22,923$).²⁹⁸ Treatment was discontinued either at discharge from the hospital or on day 28 of the hospital stay; 93% of the patients had STEMI, and approximately 54% of the patients received a fibrinolytic agent. The risk of reinfarction during treatment was 18% lower among patients who received metoprolol (2% versus 2.5%; $p = 0.001$). The overall in-hospital mortality rates were 7.7% in the metoprolol treatment group and 7.8% in the placebo group (odds ratio 0.99; 95% CI 0.92 to 1.05; $p = 0.69$). Allocation to metoprolol was associated with a significant 22% reduction in death attributed to arrhythmia (1.7% versus 2.2%; $p = 0.0002$), but there was a 29% increase in death attributed to cardiogenic shock among the metoprolol treatment group (2.2% versus 1.7%; $p = 0.0002$).

At least 32 randomized trials including nearly 27,000 patients have been conducted to determine the effect of β-blockade on long-term survival after acute MI, and several meta-analyses have been published.^{304,307,308} The Norwegian Multicenter Study Group randomized 1884 patients to receive double-blind treatment with either oral timolol or placebo beginning 7 to 28 days after acute MI.³⁰⁹ The cumulative mortality rate at 33 months was 39% lower in the timolol group than in the placebo group (10.6% versus 17.5%; $p = 0.0005$), and the sudden-death rate at 33 months was reduced by 45% (7.7% versus 13.9%; $p = 0.0001$). After continued follow-up for up to 6 years, a significant difference in mortality was maintained.³¹⁰ The Beta-Blocker Heart Attack Trial (BHAT) demonstrated that treatment with propranolol beginning 5 to 21 days after acute MI also reduced mortality during an average follow-up period of 25 months.³¹¹ A pooled analysis of 31 long-term trials found that β-blocker therapy was associated with a 23% reduction in the odds of death (95% CI 15 to 31).³⁰⁸ According to that analysis, the calculated number of patients needed to treat (NNT) for 2 years with a β-blocker to avoid one death is 42, which is less than the calculated NNT for antiplatelet therapy, which is 153.³⁰⁸

The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) study is an important trial that was not available for inclusion in the pooled analyses discussed earlier.³¹² The CAPRICORN study randomized 1959 patients with a left ventricular EF 40% or lower to carvedilol or placebo beginning 3 to 21 days after acute MI. Forty-six percent of the patients had received reperfusion therapy, and 97% had received an angiotensin-converting enzyme (ACE) inhibitor for at least 48 hours before randomization. After an average follow-up period of 1.3 years, a 23% reduction was found for all-cause mortality (12% versus 15%; hazard ratio 0.77; 95% CI 0.60 to 0.98; $p = 0.031$), identical to that reported in a meta-analysis of previous randomized trials.³⁰⁸ The CAPRICORN trial supports the conclusion that β-blockade reduces mortality after acute MI even among patients who receive reperfusion therapy and ACE inhibitors for left ventricular dysfunction.

The 2007 Focused Update of the ACC/AHA 2004 Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction includes several modifications of the 2004 guidelines and a new Class III recommendation.²¹ The three Class I recommendations regarding oral β-blocker therapy are as follows: (1) oral β-blocker therapy should be initiated in the first 24 hours for patients who do not have any of the

following: (a) signs of heart failure, (b) evidence of a low output state, (c) increased risk for cardiogenic shock (age > 70 years, systolic blood pressure < 120 mm Hg, sinus tachycardia > 110 bpm or heart rate < 60 bpm, and increased time since onset of symptoms of STEMI), or (d) other relative contraindications to β -blockade (PR interval > 0.24 seconds, second- or third-degree heart block, active asthma, or reactive airway disease); (2) patients with early contraindications within the first 24 hours of STEMI should be reevaluated for candidacy for β -blocker therapy as secondary prevention; and (3) patients with moderate or severe LV failure should receive β -blocker therapy as secondary prevention with a gradual titration scheme. There are Class IIa and III recommendations regarding intravenous β -blockade in patients with STEMI. The Class IIa recommendation states that it is reasonable to administer an IV β -blocker at the time of presentation to STEMI patients who are hypertensive and who do not have any of the following: (1) signs of heart failure, (2) evidence of low output state, (3) increased risk for cardiogenic shock (discussed earlier), or (4) other relative contraindications to β -blockade (discussed earlier). The Class III recommendations are that IV β -blockers should not be administered to STEMI patients who have any of the following: (1) signs of heart failure, (2) evidence of a low output state, (3) increased risk for cardiogenic shock, or (4) other relative contraindications to β -blockade.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Acute MI triggers neurohormonal activation that is characterized by elevated plasma renin activity and aldosterone, and plasma renin activity was found to be an independent predictor of cardiovascular mortality among patients who were enrolled in the Survival and Ventricular Enlargement (SAVE) trial.³¹³ ACE inhibitors have been shown to attenuate left ventricular enlargement after acute MI.³¹⁴ Multiple clinical trials have demonstrated that ACE inhibitors reduce mortality after acute MI. The GISSI-3 trial randomized 19,394 patients with acute MI, with or without ST segment elevation, to an oral lisinopril treatment group or an open control group within 24 hours of symptom onset.⁹⁰ Seventy-one percent of the patients received fibrinolytic therapy. Six-week mortality was 11% lower among patients in the lisinopril treatment group than it was for those in the control group (6.3% versus 7.1%; odds ratio 0.88; 95% CI 0.79 to 0.99). The ISIS-4 trial randomized 58,050 patients with acute MI to receive oral captopril or placebo within 24 hours of symptom onset.⁹¹ Seventy-nine percent of the patients had ST segment elevation on the initial ECG, and 70% of eligible patients received fibrinolytic therapy, predominantly with streptokinase. Five-week mortality was 7% lower among patients who received captopril than among those in the control group (7.19% versus 7.69%; 95% CI 1 to 13; $p = 0.02$). The individual patient data from ISIS-4 and GISSI-3 were combined with the data from two other large trials, creating a database of 98,496 patients, who were randomized to ACE inhibitor treatment or control groups during the acute phase (0 to 36 hours) of acute MI.³¹⁵ Thirty-day mortality was 7% lower among patients who received an ACE inhibitor (7.1% versus 7.6%; 95% CI 2 to 11; $p = 0.004$). The absolute benefit of ACE inhibitor therapy was greater in patients with anterior MI.

Three additional trials have investigated the efficacy of ACE inhibitors in patients with left ventricular dysfunction or CHF: the SAVE study,³¹⁶ the Acute Infarction Ramipril Efficacy (AIRE) study,³¹⁷ and the Trandolapril Cardiac Evaluation (TRACE) study.³¹⁸ The SAVE study enrolled 2231 patients with an acute MI, no overt CHF, and a left ventricular EF 40% or lower as measured by radionuclide ventriculography.³¹⁶ The patients were randomized to double-blind treatment with captopril or placebo 3 to 16 days after acute MI. After an average follow-up period of 42 months, all-cause mortality was reduced by 19% (20% versus 25%; 95% CI 3 to 32; $p = 0.019$). The risk reduction was 22% among patients treated with fibrinolytic therapy (33% of the patients) compared with 17% among patients who were not. Captopril reduced the risk of recurrent MI by 25% (95% CI 5 to 40; $p = 0.015$).³¹⁹ The AIRE study enrolled 2006 patients with an acute MI and clinical or radiologic evidence of CHF.³¹⁷ The patients were randomized to double-blind treatment with ramipril or placebo beginning 3 to 10 days after acute MI. After average follow-ups of 15 months, all-cause mortality was reduced by 27% (17% versus 23%; 95% CI 11 to 40; $p = 0.002$). The TRACE study enrolled 1749 patients with an acute MI and an echocardiographic left ventricular EF 35% or lower.³¹⁸ The patients were randomized to double-blind treatment with trandolapril or placebo beginning 3 to 7 days after acute MI. The relative risk (RR) of death from any cause in the trandolapril group, as compared with the control group, was 0.78 (95% CI 0.67 to 0.91; $p = 0.001$). After follow-up for a minimum of 6 years, the life expectancy of patients was 4.6 years for patients who received placebo versus 6.2 years for those who were treated with trandolapril, a median increase of 15.3 months.³²⁰ A pooled analysis of the data from individual patients who were enrolled in the SAVE, AIRE, and TRACE trials concluded that the mortality rate after a median treatment duration of 31 months was reduced from 29.1% in control patients to 23.4% in the ACE-inhibitor group (odds ratio 0.74; 95% CI 0.66 to 0.83; $p < 0.0001$).³²¹

The Register of Information and Knowledge about Swedish Heart Intensive Care Admissions (RIKS-HIA) enrolled 105,225 patients with acute MI who were not treated with ACE inhibitors on admission.³²² The association between treatment with an ACE inhibitor at discharge from the hospital and the outcome at 1 year was evaluated using Cox regression analyses adjusted for medications at discharge and the propensity score. Among the entire cohort, treatment with an ACE inhibitor was associated with a 24% reduction in mortality (RR 0.76; 95% CI 0.73 to 0.80), but among patients without heart failure, a significant benefit was observed only in patients with renal dysfunction.

Two randomized clinical trials compared captopril with an angiotensin receptor blocker (ARB) in high-risk acute MI patients: the Optimal Trial in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL)³²³ and the Valsartan in Acute Myocardial Infarction Trial (VALIANT).³²⁴ The OPTIMAAL trial enrolled 5477 patients with acute STEMI who met any of the following entry criteria: symptoms or signs of CHF, left ventricular EF less than 35%, or new anterior Q waves. Fifty-four percent of the patients received fibrinolytic agents. The patients were randomized to double-blind treatment with either losartan, titrated to a target dose of 50 mg daily, or captopril, titrated

to a target dose of 50 mg three times daily, within 10 days of symptom onset. After an average follow-up period of 2.7 years, no significant difference in all-cause mortality was found between the losartan and the captopril treatment groups (18% versus 16%; RR 1.13; 95% CI 0.99 to 1.28; $p = 0.07$). The prespecified criterion for noninferiority was not satisfied. The VALLANT trial enrolled 14,703 patients with acute MI complicated by clinical or radiographic signs of CHF or reduced left ventricular EF ($\leq 35\%$ by echocardiography or contrast ventriculography or $\leq 40\%$ by radionuclide ventriculography), or both. Approximately 50% of the patients underwent reperfusion therapy; 35%, fibrinolytic therapy; and 15%, primary PCI. Within 10 days after the acute MI, the patients were randomly assigned to three treatment groups: valsartan monotherapy, captopril monotherapy, or the combination of valsartan and captopril. After an average follow-up period of 24.7 months, all-cause mortality was not significantly different for the three groups: valsartan 19.9%, captopril 19.5%, and the combination 19.3%. The investigators concluded that valsartan is at least as effective as captopril, because the criterion for noninferiority of valsartan relative to captopril was met.

Both aldosterone and angiotensin II, a potent stimulus of adrenal aldosterone production, are increased in patients with CHF despite chronic treatment with an ACE inhibitor. Aldosterone exerts numerous adverse cardiovascular effects, including increased myocardial collagen deposition and fibrosis and cardiomyocyte apoptosis.³²⁵ Eplerenone, a selective aldosterone blocker, was studied in a multicenter, international, randomized, double-blind, placebo-controlled trial called the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS).³²⁶ The EPHESUS investigators enrolled 6632 patients with acute MI complicated by left ventricular dysfunction (EF less than 40%) plus either CHF or diabetes.³²⁶ The patients were randomized to double-blind treatment with eplerenone or placebo beginning 3 to 14 days after acute MI. At the time of enrollment, 86% of the patients were taking an ACE inhibitor or ARB, and 75% were taking a β -blocker. During a mean follow-up period of 16 months, significantly fewer deaths occurred in the eplerenone group (478 of 3319 patients) than in the placebo group (554 of 3313 patients) (14.4% versus 16.7%; RR 0.85; 95% CI 0.75 to 0.96; $p = 0.008$). A reduction in the rate of sudden death from cardiac causes (RR 0.79; 95% CI 0.64 to 0.97; $p = 0.03$) also was observed. Serious hyperkalemia, defined as a serum potassium of 6 mmol/L or more, occurred in 5.5% of patients in the eplerenone group versus 3.9% of those in the placebo group ($p = 0.002$).

The ACC/AHA Practice Guidelines include the following Class I recommendations regarding inhibitors of the renin-angiotensin-aldosterone system: (1) ACE inhibitors should be started and continued indefinitely in all patients recovering from STEMI with LVEF less than or equal to 40% and for those with hypertension, diabetes, or chronic kidney disease, unless otherwise contraindicated; (2) ACE inhibitors should be started and continued indefinitely in patients recovering from STEMI who are not lower risk (lower risk defined as those with normal LVEF in whom cardiovascular risk factors are well controlled and revascularization has been performed), unless contraindicated; (3) the use of angiotensin receptor blockers is recommended in patients

who are intolerant of ACE inhibitors and have heart failure or have had an MI with LVEF less than or equal to 40%; (4) it is beneficial to use angiotensin receptor blocker therapy in other patients who are ACE-inhibitor intolerant and have hypertension; (5) the use of aldosterone blockade in post-MI patients without significant renal dysfunction (serum creatinine less than 2.5 mg/dL in men and less than 2 mg/dL in women) or hyperkalemia (serum potassium ≥ 5 mEq/L) is recommended in patients who are already receiving therapeutic doses of an ACE inhibitor and β -blocker, have an LVEF of less than or equal to 40%, and have either diabetes or heart failure.²¹ Intravenous ACE inhibitors should not be given within 24 hours of an acute MI because of the risk of hypotension.

ANTIARRHYTHMIC DRUGS

Both atrial and ventricular arrhythmias are common in patients with acute MI. The incidence of atrial fibrillation was 10.4% among 40,891 patients who were enrolled in the GUSTO-I trial.³²⁷ Patients in whom atrial fibrillation developed after admission were more likely to have a stroke or die within 30 days after acute MI. Among patients enrolled in the TRACE study, which enrolled patients with an acute MI and a left ventricular EF less than 35%, atrial fibrillation occurred in 21% of patients and was associated with a 50% increase in adjusted mortality.³²⁸ Intravenous β -adrenergic blockade is the preferred therapy for patients with sustained atrial fibrillation or atrial flutter that is not associated with hemodynamic compromise, whereas sustained atrial fibrillation or flutter that is associated with hemodynamic compromise is an indication for synchronized cardioversion. Intravenous amiodarone is indicated for treatment of atrial fibrillation that does not respond to electrical cardioversion or recurs after cardioversion. Sustained atrial fibrillation should be treated with anticoagulants.

The incidence of primary ventricular fibrillation, defined as that occurring within 48 hours of acute MI and in the absence of cardiogenic shock or severe CHF, was 4.7% among a cohort of 5020 patients hospitalized for an uncomplicated acute MI in Worcester, Massachusetts, during 11 1-year periods between 1975 and 1997.³²⁹ The incidence of primary ventricular fibrillation in the GISSI-1 trial was not significantly different in the streptokinase and control groups (2.73% versus 2.93%; RR 0.93; 95% CI 0.75 to 1.15).³³⁰ A meta-analysis of 15 randomized trials of fibrinolytic therapy for acute MI confirmed that the likelihood of this arrhythmia is not altered by fibrinolytic therapy, with an incidence of ventricular fibrillation during the first hospital day of 2.99% for both the fibrinolytic treatment and placebo groups.³³¹ There is evidence, however, that fibrinolytic therapy exerts a protective effect against secondary ventricular fibrillation, defined as ventricular fibrillation in patients with acute MI complicated by CHF or shock.^{331,332} Thus, the meta-analysis of 15 fibrinolytic trials found that the odds ratio for the development of ventricular fibrillation at any time during hospitalization in the fibrinolytic treatment group was 0.83 (95% CI 0.76 to 0.90; $p < 0.0001$).³³¹

Primary ventricular fibrillation is an independent predictor of in-hospital mortality whether it occurs early (up to 4 hours) or late (after 4 to 48 hours) after the onset of acute MI.³³³ Among 9720 patients with a first STEMI who were enrolled in the GISSI-2 fibrinolytic trial, 356 of the 7755

patients who were in Killip class I at entry developed primary ventricular fibrillation.³³³ Early primary ventricular fibrillation occurred in 302 patients (3.7%) and late primary ventricular fibrillation occurred in 54 patients (0.6%); 226 patients had ventricular fibrillation within 1 hour of the onset of acute MI symptoms. In-hospital mortality rates were 13% among patients with late primary ventricular fibrillation (RR 3.80; 95% CI 1.80 to 8.02) and 7% among patients with early primary ventricular fibrillation (RR 2.00; 95% CI 1.29 to 3.12), compared with 4% among patients in Killip class I on admission in whom ventricular fibrillation did not develop. The in-hospital mortality rate associated with primary ventricular fibrillation was much higher in the Worcester Heart Attack Study, with an overall case-fatality rate of 44%, although improved survival was observed in patients who had primary ventricular fibrillation in the 1990s.³²⁹

Among 11,712 patients enrolled in the GISSI-1 study, secondary ventricular fibrillation occurred in 311 patients (2.7%).³³² The incidence of secondary ventricular fibrillation within 24 hours of acute MI was similar among the patients treated with streptokinase and the control group, whereas streptokinase halved the frequency of secondary ventricular fibrillation later than 24 hours after admission (27/5860 versus 60/5852; RR 0.45; 95% CI 0.29 to 0.70). The protective effect of streptokinase was even greater among patients who were treated within 3 hours of symptom onset (9/3016 versus 39/3078; RR 0.23; 95% CI 0.12 to 0.45). In-hospital mortality was higher among patients with secondary ventricular fibrillation: 27.1% versus 17.3% for patients in Killip class II (RR 1.77; 95% CI 1.28 to 2.45) and 48.1% versus 35.3% for patients in Killip class III (RR 1.70; 95% CI 0.95 to 3.02). Secondary ventricular fibrillation did not affect in-hospital mortality among the patients in Killip class IV (67.9% with secondary ventricular fibrillation versus 71.9% without secondary ventricular fibrillation; RR 0.83; 95% CI 0.44 to 1.55).

Although primary and secondary ventricular fibrillation both are associated with an increased risk of in-hospital death, patients who survive to be discharged from the hospital after experiencing either type have a good prognosis. Among the patients who were enrolled in the GISSI-1 and GISSI-2 trials and had nonfatal primary ventricular fibrillation, 6-month mortality after hospital discharge among patients with the primary type was not significantly different from that in patients who did not have this arrhythmia.^{333,334} In GISSI-2, patients who survived the hospital phase of an acute MI complicated by secondary ventricular fibrillation had a 1-year mortality of 10.4%, compared with 13.9% among patients who did not have secondary ventricular fibrillation (20/193 versus 322/2319; RR 0.72; 95% CI 0.44 to 1.15).³³²

Partly on the basis of the results of one double-blind, randomized study,³³⁵ an editorial published in 1978 concluded that there was justification for routine prophylactic administration of lidocaine to all patients with acute MI to prevent primary ventricular fibrillation.³³⁶ Subsequent studies of prophylactic lidocaine in acute MI, including more than 20 randomized trials and at least four meta-analyses, concluded that lidocaine reduces the incidence of ventricular fibrillation but increases mortality.³³⁷ Therefore, according to the ACC/AHA Practice Guidelines that

were published in 2004, prophylactic antiarrhythmic therapy is not recommended with use of fibrinolytic agents.²⁰ Also, the routine use of lidocaine is not indicated for suppression of isolated ventricular premature beats, couplets, runs of accelerated idioventricular rhythm, and nonsustained ventricular tachycardia. The guidelines favor intravenous amiodarone for treatment of sustained monomorphic ventricular tachycardia.

Although ventricular ectopy is a marker of an increased risk of sudden death in survivors of acute MI, trials of chronic, oral antiarrhythmic drugs have not shown beneficial effects. The Cardiac Arrhythmia Suppression Trial (CAST) I and CAST II found that treatment with the class IC drugs encainide and flecainide, or the class IA drug moricizine, increased mortality in survivors of acute MI.^{338,339} *d*-Sotalol, a potassium channel blocker, also increased mortality among survivors of MI in the Survival with Oral *d*-Sotalol (SWORD) randomized trial.³⁴⁰ Clinical trials of amiodarone, a class III antiarrhythmic drug, suggested that it may reduce the incidence of ventricular fibrillation or arrhythmic death among survivors of acute MI.^{341,342}

The implantable cardioverter-defibrillator (ICD) has become the standard of care for the prevention of sudden death in survivors of acute MI.³⁴³ There are two Class I indications for an ICD after STEMI: (1) an ICD is indicated for patients with ventricular fibrillation or hemodynamically significant sustained ventricular tachycardia later than 2 days after STEMI, provided that the arrhythmia is not judged to be due to transient or reversible ischemia or reinfarction. (2) An ICD is indicated for patients without spontaneous ventricular fibrillation or sustained ventricular tachycardia more than 48 hours after STEMI whose STEMI occurred at least 1 month previously, who have a left ventricular EF between 31% and 40%, demonstrated additional evidence of electrical instability (e.g., nonsustained ventricular tachycardia), and who have inducible ventricular fibrillation or sustained ventricular tachycardia on electrophysiology testing.²⁰

CALCIUM ANTAGONISTS

No Class I indications are provided for calcium channel blockers in patients with acute MI because neither individual clinical trials nor analyses of the pooled results of multiple trials showed a reduction in mortality after acute MI.^{307,344,345} A randomized study that compared diltiazem with placebo starting 3 to 15 days after acute MI found that diltiazem therapy was associated with an increased risk of cardiac events in patients with radiographic evidence of pulmonary congestion.³⁴⁶ The same trial concluded that diltiazem increases the risk of late-onset CHF in patients with a left ventricular EF less than 40%.³⁴⁷ Thus, there are two Class III recommendations for calcium channel blockers in acute MI: (1) Diltiazem and verapamil are contraindicated in patients with STEMI and associated systolic left ventricular dysfunction and CHF. (2) Nifedipine (immediate-release form) is contraindicated in the treatment of STEMI because of the reflex sympathetic activation, tachycardia, and hypotension associated with its use.²⁰

LIPID-LOWERING AGENTS

Numerous trials have evaluated the effects of statins on coronary events in patients with acute and chronic CAD, but

none of the trials restricted enrollment to patients with STEMI or provided subgroup analyses of the outcomes among patients with STEMI before enrollment. The Scandinavian Simvastatin Survival Study (4S) was the first clinical trial to demonstrate significant reductions in total mortality and coronary heart disease mortality by treatment with lipid-lowering therapy.³⁴⁸ Seventy-nine percent of the patients had a history of MI. After a median follow-up period of 5.4 years, total mortality was 12% in the placebo group versus 8% in the patients who were randomly assigned to receive simvastatin (RR 0.70; 95% CI 0.58 to 0.85; $p = 0.0003$). Also, there was a 37% reduction in the risk of undergoing a myocardial revascularization procedure. The beneficial effects of statin therapy in patients with a history of MI were confirmed by two studies that randomized patients to receive pravastatin 40 mg daily or placebo: the Cholesterol and Recurrent Events (CARE) trial³⁴⁹ and the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) trial.³⁵⁰ All patients who were enrolled in the CARE trial had a history of MI between 3 and 20 months before enrollment, and 64% of the patients enrolled in the LIPID trial had a history of MI between 3 and 36 months before enrollment.

A diagnosis of hyperlipidemia cannot be excluded during the first week after an acute MI because both total cholesterol and low-density lipoprotein (LDL) cholesterol decrease significantly during the first week after an acute MI.³⁵¹ There are numerous Class I recommendations for lipid management in patients who have had a STEMI. Although the current Class I guidelines recommend a target LDL cholesterol level less than 100 mg/dL, future guidelines may reflect data that support more aggressive treatment to achieve the goal of an LDL cholesterol level of less than 70 mg/dL.³⁵²⁻³⁵⁴

INTRA-AORTIC BALLOON COUNTERPULSATION

Several randomized trials have evaluated the utility of intra-aortic balloon counterpulsation in high-risk patients with acute MI not complicated by cardiogenic shock. The Second Primary Angioplasty in Myocardial Infarction (PAMI-II) investigators randomized 436 patients with a high-risk acute MI to insertion of an intra-aortic balloon pump (IABP) or no IABP after primary PCI.³⁵⁵ The rates of reocclusion of the IRA, reinfarction, and mortality were not significantly different, and there was a higher incidence of stroke among patients who received an IABP (2.4% versus 0%; $p = 0.03$). Also, there was no enhancement of myocardial recovery at the time of hospital discharge or 6 weeks after discharge. The Counterpulsation to Reduce Infarct Size Pre-PCI Acute Myocardial Infarction (CRISP AMI) trial was a randomized trial to determine whether insertion of an IABP before primary PCI reduces infarct size in patients with an acute anterior STEMI without cardiogenic shock.³⁵⁶ The mean infarct size, measured by cardiac magnetic resonance imaging 3 to 5 days after PCI was 42.1% of the left ventricle in the IABP group compared with 37.5% of the left ventricle in the control group ($p = 0.06$). Thus, the IABP has not been shown to be beneficial in patients with high-risk or anterior acute MI who undergo primary PCI. The use of the IABP in patients with cardiogenic shock is discussed in a subsequent section of this chapter and in the chapter on cardiogenic shock.

CORONARY ARTERY BYPASS GRAFT SURGERY

Randomized trials have not been performed to compare surgical reperfusion for acute MI with either conservative medical therapy or reperfusion by means of fibrinolytic therapy or PCI. A nonrandomized study compared the outcomes in 200 patients managed conservatively with those in 187 patients who underwent surgical reperfusion between 1972 and 1976.³⁵⁷ In-hospital mortality was 5.8% among patients who underwent CABG surgery, compared with 11.5% among patients who did not undergo myocardial reperfusion ($p < 0.08$). Among the patients who underwent coronary bypass grafting within 6 hours from the onset of symptoms of acute MI, in-hospital mortality was only 2% (2/100), compared with 10.3% (9/87) among the patients who underwent surgery more than 6 hours after the onset of symptoms.

Although registry data indicate that CABG surgery within 24 hours of an acute STEMI is associated with a marked increase of in-hospital mortality,³⁵⁸ emergency surgical revascularization should be considered in certain subsets of patients. Emergency CABG surgery is a reasonable option in patients with cardiogenic shock and coronary anatomy poorly suited for PCI (e.g., severe stenosis of the left main coronary artery). Among patients enrolled in the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock? (SHOCK) trial, survival rates were similar for CABG surgery and for PCI.³⁵⁹ The 2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft Surgery includes four Class I, two Class IIa, and two Class III recommendations regarding CABG in patients with acute MI³⁶⁰ (Box 30.6).

Mortality after CABG surgery remains elevated during the first week after an acute MI.³⁵⁸ Therefore, the 2004 ACC/AHA Practice Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction recommended that patients who have been stabilized after STEMI and who have incurred a significant fall in LV function should have their surgery delayed to allow for myocardial recovery.²⁰

An additional reason to delay surgery in stable patients is to permit recovery of platelet function in patients who have received a P2Y₁₂ inhibitor. Red blood cell transfusion of 4 units or more after CABG was an independent predictor of 1-year mortality among 1491 patients with ACS who underwent CABG.³⁶¹ There are conflicting data regarding the impact of P2Y₁₂ inhibitors on the risk of bleeding and transfusion after CABG. One retrospective analysis of 596 patients with ACS who underwent CABG found that exposure to clopidogrel within 5 days of surgery increased the risk of major bleeding and reoperation.³⁶² Among 1539 patients with ACS who were enrolled in the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial and underwent CABG before discharge, CABG within 5 days of the last clopidogrel dose was not associated with higher rates of transfusion or major bleeding compared with the rates among patients who did not receive any clopidogrel before CABG.³⁶³ Administration of clopidogrel within 5 days before CABG was associated with a modestly increased risk of red blood cell transfusion but was not significantly associated with reoperation for bleeding among 332 patients who were enrolled in the Duke Databank between January 1999 and December 2003.³⁶⁴ According to the 2011 ACCF/AHA Guideline for CABG, clopidogrel and ticagrelor should be

Box 30.6 CABG in Patients with Acute MI

Class I

1. Emergency CABG is recommended in patients with acute MI in whom (1) primary PCI has failed or cannot be performed, (2) coronary anatomy is suitable for CABG, and (3) persistent ischemia of a significant area of myocardium at rest or hemodynamic instability refractory to nonsurgical therapy is present.
2. Emergency CABG is recommended in patients undergoing surgical repair of a postinfarction mechanical complication of MI, such as ventricular septal rupture, mitral valve insufficiency because of papillary muscle infarction or rupture, or free wall rupture.
3. Emergency CABG is recommended in patients with cardiogenic shock and who are suitable for CABG irrespective of the time interval from MI to onset of shock and time from MI to CABG.
4. Emergency CABG is recommended in patients with life-threatening ventricular arrhythmias (believed ischemic in origin) in the presence of left main stenosis greater than or equal to 50% or three-vessel CAD.

Class IIa

1. The use of CABG is reasonable as a revascularization strategy in patients with multivessel CAD with recurrent angina or MI within the first 48 hours of STEMI presentation as an alternative to a more delayed strategy.
2. Early revascularization with PCI or CABG is reasonable for selected patients older than 75 years of age with ST segment elevation or left bundle branch block who are suitable for revascularization irrespective of the time interval from MI to onset of shock.

Class III

1. Emergency CABG should not be performed in patients with persistent angina and a small area of viable myocardium who are stable hemodynamically.
2. Emergency CABG should not be performed in patients with no-reflow (successful epicardial reperfusion with unsuccessful microvascular reperfusion).

CABG, coronary artery bypass graft; CAD, coronary artery disease; MI, myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST segment elevation myocardial infarction

From Hillis LD, Smith PK, Anderson JL, et al: 2011 ACCF/AHA guideline for coronary artery bypass graft surgery: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2011;58:e123-e210.

discontinued for at least 5 days before surgery and prasugrel for at least 7 days to limit blood transfusions, while clopidogrel and ticagrelor should be discontinued for at least 24 hours in patients referred for urgent CABG.³⁶⁰ Finally, the guideline includes a Class I recommendation that aspirin (100 mg to 325 mg) should be administered to CABG patients preoperatively.³⁶⁰

MANAGEMENT OF COMPLICATIONS

PERICARDITIS AND PERICARDIAL TAMPONADE

Pericarditis, defined as the detection of a pericardial friction rub, was diagnosed in 20% (141/703) of patients who were

enrolled in the Multicenter Investigation of the Limitation of Infarct Size (MILIS).³⁶⁵ The frequency of pericarditis was higher in patients with Q wave MI than in those with non-Q wave MI (25% versus 9%; $p < 0.001$). Pericarditis was associated with a lower admission left ventricular EF (42% versus 48%; $p < 0.001$) and a higher incidence of CHF (47% versus 26%; $p < 0.001$). Pericarditis was accompanied by pleuritic or positional chest pain in 70% of patients. Diagnostic electrocardiographic changes usually are absent in patients with infarction-associated pericarditis.³⁶⁶ A prospective study of 423 patients with acute MI found that only 1 of the 31 patients with pericardial friction rubs had diagnostic ST segment changes.³⁶⁶

The GISSI investigators reported the frequency of pericardial involvement in patients who were enrolled in the GISSI-1 ($n = 11,806$) and GISSI-2 ($n = 12,381$) trials.³⁶⁷ The incidence of pericardial involvement was lower among patients who received fibrinolytic therapy than among patients in the control groups (6.7% versus 12%). Earlier treatment with fibrinolytic therapy was associated with a lower risk of pericardial involvement. Although pericardial involvement was associated with a higher long-term mortality, it was not an independent prognostic factor because it was strongly associated with the extent of infarction as determined by ECG, peak creatine kinase, and echocardiography.

The ACC/AHA Practice Guidelines recommend aspirin for treatment of pericarditis after STEMI.²⁰ Colchicine or acetaminophen is recommended for patients who do not respond to aspirin. Corticosteroids and nonsteroidal anti-inflammatory drugs are discouraged because of an increased risk of scar thinning and infarct expansion. Finally, anticoagulation should be discontinued if a pericardial effusion is detected.

Hemorrhagic pericarditis and free wall rupture are two potential mechanisms of cardiac tamponade after acute MI. Among 102,060 patients with STEMI who were enrolled in seven randomized clinical trials and received fibrinolytic therapy, cardiac tamponade developed in 1018 patients (1%).³⁶⁸ Among the patients with tamponade, 153 also had a ventricular septal rupture or acute mitral regurgitation, and 865 had isolated cardiac tamponade. The adjusted 30-day mortality among 7-day survivors with tamponade was significantly increased (hazard ratio 7.9; 95% CI 4.7 to 13.5; $p < 0.0001$). Pericardial tamponade accounted for 1.4% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or the randomized trial.³⁶⁹

RECURRENT ISCHEMIA OR INFARCTION

Recurrent infarction (reinfarction) after an initial STEMI is relatively uncommon, but it often is an end point for clinical trials, because reinfarction is associated with increased morbidity and mortality.^{370,371} Symptomatic recurrent MI during the index hospitalization occurred in 4.2% (836/20,101) of patients who were enrolled in four clinical trials of various fibrinolytic agents.³⁷¹ Recurrent MI occurred a median of 2.2 days after the initial MI and was associated with increased mortality rates at both 30 days (16.4% versus 6.2%; $p < 0.001$) and 2 years (hazard ratio 2.11, $p < 0.001$). In-hospital reinfarction occurred in 4.3% of patients (2258/55,911) a median of 3.8 days after fibrinolytic therapy in the GUSTO

I and GUSTO III trials.³⁷⁰ The rates of reinfarction were 4.3% for alteplase, 4.5% for reteplase, and 4.1% for streptokinase ($p = 0.55$). Patients with in-hospital reinfarction had higher mortality at 30 days (11.3% versus 3.5%; odds ratio 3.5; $p < 0.001$) and from 30 days to 1 year (4.7% versus 3.2%; hazard ratio 1.5; $p < 0.001$).³⁷⁰ Compared with patients who did not have reinfarction, patients with reinfarction had higher rates of CHF (31.9% versus 13.9%) and cardiogenic shock (15.9% versus 2.4%).

The frequency of recurrent ischemia or reinfarction after an initial STEMI depends on the modality of reperfusion and the adjunctive therapy employed. One of the purported advantages of primary PCI over fibrinolytic therapy is a decreased rate of reinfarction. The 30-day rates of reinfarction in the DANAMI-2 trial were 6.3% (49/782) among patients who were randomized to fibrinolytic therapy compared with 1.6% (13/790) among patients who were assigned to the angioplasty group ($p < 0.001$).²¹⁴ In a meta-analysis of 13 randomized trials of primary angioplasty versus fibrin-specific agents, the frequency of nonfatal reinfarction was 3% (74/2753) among patients randomized to angioplasty, compared with 6% (172/2757) among patients assigned to fibrinolytic therapy (odds ratio 0.42; 95% CI 0.31 to 0.55).²⁰⁹

There is evidence that coronary revascularization reduces the risk of reinfarction after fibrinolytic therapy. Among patients who were enrolled in four clinical trials of various fibrinolytic drugs, PCI or CABG surgery was performed during the index hospitalization in 26.1% (5238/20,039) of the patients and was associated with lower rates of both in-hospital recurrent MI (1.4% versus 4.7%, $p < 0.001$) and 2-year mortality.³⁷¹

A variety of antithrombotic and antiplatelet therapies have been shown to reduce the risk of reinfarction after STEMI. In a trial that randomized 20,506 patients with STEMI to either enoxaparin or UFH as adjunctive treatment after fibrinolytic therapy, the rates of reinfarction at 30 days were 3% for the enoxaparin group (309/10,256) compared with 4.5% for the UFH group (458/10,223) (RR 0.67; 95% CI 0.58 to 0.77; $p < 0.001$).¹³¹ A meta-analysis of 11 clinical trials found that administration of abciximab was associated with a reduction in the 30-day reinfarction rates among patients who underwent primary angioplasty (1% versus 1.9%; odds ratio 0.56; 95% CI 0.33 to 0.94; $p = 0.03$) and among patients who received fibrinolytic therapy (2.3% versus 3.6%; odds ratio 0.64; 95% CI 0.54 to 0.75; $p < 0.001$).²⁸⁸

Numerous clinical trials have investigated the effect of warfarin alone or in combination with aspirin on the risk of reinfarction and other events in patients with ACS, but most of the studies were not restricted to patients with STEMI, the target international normalized ratio (INR) has varied, and conflicting results have emerged.^{372,373} The Warfarin Re-Infarction Study randomized 1214 patients to receive placebo or warfarin (target INR 2.8 to 4.8) after an average interval between the index MI and enrollment of 27 days.³⁷⁴ Approximately 70% of patients had Q waves on the baseline ECG, most patients did not receive reperfusion therapy, and all patients were advised not to take aspirin or other antiplatelet drugs. During an average treatment period of 37 months, the rate of reinfarction was significantly reduced by warfarin compared with placebo (82/607 versus 124/607; RR 34%; 95% CI 19% to 54%; $p = 0.0007$).

The Antithrombotics in the Secondary Prevention of Events in Coronary Thrombosis-2 (ASPECT-2) study randomized 999 patients to receive one of three antithrombotic regimens: aspirin 80 mg daily, warfarin (target INR 3.0 to 4.0), or the combination of aspirin 80 mg daily and warfarin (target INR 2.0 to 2.5).³⁷⁵ Patients were enrolled within 8 weeks of hospitalization for either UA (13%) or Q wave or non-Q wave MI. During a median follow-up period of 12 months, the primary composite end point of MI, stroke, or death was significantly less frequent for the two groups that received warfarin, but warfarin did not reduce the risk of MI, and it increased the risk of both major and minor bleeding.

The APRICOT-2 trial randomized 308 patients with a patent IRA within 48 hours after fibrinolytic therapy to receive either aspirin alone (80 mg daily) or aspirin plus warfarin for 3 months (target INR 2.0 to 3.0).³⁷⁶ The rate of reinfarction during 3 months of follow-up was 2% (3/135) for combination therapy, compared with 8% (11/139) for aspirin alone ($p < 0.05$). The Warfarin, Aspirin, Reinfarction Study (WARIS II) randomly assigned 3630 patients who were hospitalized for an acute MI to one of three treatment groups: warfarin alone (with a target INR of 2.8 to 4.2), aspirin alone (160 mg daily), or the combination of aspirin 75 mg daily and warfarin (target INR 2.0 to 2.5).³⁷⁷ Fibrinolytic drugs were administered to 53% to 55% of the patients in each group. During a mean observation period of 4 years, the rates of reinfarction were significantly less in both groups of patients who received warfarin: 9.7% (117/1206) for aspirin alone, 7.4% (90/1216) for warfarin alone (RR 0.74; 95% CI 0.55 to 0.998; $p = 0.03$), and 5.7% (69/1208) for aspirin plus warfarin (RR 0.56; 95% CI 0.41 to 0.78; $p < 0.001$). Another study that used a target INR of 1.5 to 2.5 found that the addition of warfarin to aspirin 81 mg daily did not reduce the rate of reinfarction compared with aspirin monotherapy (162 mg daily).³⁷⁸ The combination of aspirin 80 mg daily with low, fixed-dose warfarin (1 mg or 3 mg) was not superior to aspirin 160 mg daily in patients with a recent STEMI or NSTEMI.³⁷⁹ Thus, the clinical trials suggest that warfarin is superior to placebo, that the combination of aspirin and warfarin is superior to aspirin alone if the target INR is sufficiently high, and that the risk of major bleeding is increased by adding warfarin to aspirin. Also, the published data should not be extrapolated to patients who receive dual antiplatelet therapy (aspirin plus a thienopyridine) after either fibrinolytic therapy or coronary artery stenting, because most of the patients who were enrolled in the warfarin trials did not receive reperfusion therapy or a thienopyridine.

In the ISIS-2 trial, aspirin reduced the rate of in-hospital reinfarction both in the patients who received streptokinase and in those who did not receive fibrinolytic therapy. Higher platelet counts were associated with an increased risk of reinfarction among patients with STEMI for whom treatment consisted of aspirin plus a fibrinolytic drug.³⁸⁰ The addition of clopidogrel to aspirin abolishes the increased risk of reinfarction as the platelet count increases.³⁸⁰ In the CLARITY study, the rate of recurrent MI after fibrinolytic therapy was 4.1% among patients treated with clopidogrel and aspirin, compared with 5.9% among patients who received placebo and aspirin (representing a 31% reduction in odds).¹⁰⁶

Clinical trials have demonstrated that β -blockers, ACE inhibitors, and statins also reduce the risk of reinfarction after acute MI, although most of the trials enrolled patients with both STEMI and NSTEMI, and subgroup analyses of outcomes in patients with STEMI were not published. Compared with metoprolol started 6 days after tPA for acute STEMI, metoprolol started within 2 hours of tPA was associated with lower rates of reinfarction (5.1% versus 2.7%; $p = 0.02$) and recurrent chest pain (24.1% versus 18.8%; $p < 0.02$) at 6 days.³⁰⁵ The Norwegian Multicenter Study Group randomly assigned 1884 patients to double-blind treatment groups, to receive either oral timolol or placebo, beginning 7 to 28 days after acute MI.³⁰⁹ The cumulative reinfarction rate at 33 months was 28% lower in the timolol group than in the placebo group (14.4% versus 20.1%; $p = 0.0006$). The CAPRICORN study randomized 1959 patients with a left ventricular EF of 40% or less to receive carvedilol or placebo beginning 3 to 21 days after acute MI. Forty-six percent of the patients had received reperfusion therapy and 97% had received an ACE inhibitor for at least 48 hours before beginning the study treatment. After an average follow-up period of 1.3 years, the rate of nonfatal MI was significantly lower in the carvedilol group than in the placebo group (3% versus 6%; hazard ratio 0.59; 95% CI 0.39 to 0.90; $p = 0.014$).

The GISSI 3 trial did not show an effect of lisinopril on the rate of reinfarction after 6 weeks.⁹⁰ Although the AIRE³¹⁷ and TRACE³¹⁸ trials failed to show a significant effect of ramipril or trandolapril on the long-term risk of reinfarction, the SAVE study^{316,319} did observe a significant decrease in the reinfarction rate among patients who were randomly selected to receive captopril 3 to 16 days after acute MI. After an average follow-up period of 42 months, captopril reduced the risk of recurrent MI by 25% (95% CI 5% to 40%; $p = 0.015$).³¹⁹ Thus, ACE inhibitors may not reduce the short-term risk of reinfarction after acute MI, but they may decrease the long-term risk of reinfarction.

Numerous trials have evaluated the effects of statins on coronary events in patients with acute and chronic CAD, but none of the trials restricted enrollment to patients with STEMI and many of the trials pooled the data of patients with UA, NSTEMI, and STEMI. All patients who were enrolled in the CARE trial had a history of MI between 3 and 20 months before randomization; 61% were enrolled after a Q wave MI.³⁴⁹ Although the mean interval from MI to enrollment was 10 months, during a median follow-up period of 5 years there was a significantly lower rate of nonfatal MI among patients who received pravastatin compared with patients who received placebo (6.5% versus 8.3%; RR 23%; 95% CI 4% to 39%; $p = 0.02$).³⁴⁹

Data are conflicting regarding the benefit of initiating statin therapy within 14 days of the onset of ACS. At least two meta-analyses of relevant randomized controlled trials have been published.^{381,382} One analysis of 12 randomized trials concluded that statin therapy initiated within 14 days of hospital admission does not reduce the risk of death, MI, or stroke during the first 4 months after ACS.³⁸¹ Another meta-analysis of 13 randomized trials concluded that early statin therapy reduces death and cardiovascular events after 4 months of treatment.³⁸² A prospective cohort study using data from the Swedish Registry of Cardiac Intensive Care concluded that initiation of statin therapy before discharge

was associated with a 25% reduction in 1-year mortality in hospital survivors of acute MI.³⁸³

Among a cohort of 2301 patients who suffered reinfarction after administration of fibrinolytic therapy in the GUSTO I and Assessment of Safety and Efficacy of a New Thrombolytic 2 (ASSENT 2) clinical trials, reinfarction was treated with repeat fibrinolysis ($n = 864$), with revascularization ($n = 525$), or conservatively ($n = 835$).³⁸⁴ After adjustment for baseline characteristics, the 30-day mortality was significantly greater in the conservative group, 28%, compared with the repeat fibrinolysis group, 11% (odds ratio 2.2; 95% CI 1.5 to 3.1; $p < 0.001$) or the revascularization group, 11% (odds ratio 2.2; 95% CI 1.4 to 3.3; $p < 0.0001$). No significant difference was observed between the revascularization and repeat fibrinolysis groups.

The ACC/AHA Practice Guidelines provide several recommendations regarding the management of recurrent ischemia and reinfarction.²⁰ They recommend escalation of medical therapy with nitrates, β -blockers, and intravenous anticoagulation. Insertion of an IABP should be considered in patients with hemodynamic instability, poor left ventricular function, or a large area of myocardium at risk. Recurrent ischemic-type chest discomfort is a Class I indication for coronary angiography and PCI or CABG surgery in patients who are considered candidates for revascularization. There is a Class IIa recommendation for readministration of fibrinolytic therapy to patients with ischemic-type chest discomfort and recurrent ST segment elevation who are not considered candidates for revascularization or for whom coronary angiography and PCI cannot be implemented within 60 minutes of the onset of recurrent ischemia. A Class III recommendation regarding streptokinase states that it should not be readministered to patients who received a non-fibrin-specific fibrinolytic agent more than 5 days previously.

CONGESTIVE HEART FAILURE

Wu and colleagues²⁸³ described the outcomes for patients with STEMI who were enrolled in the NRMI-2 database and had CHF on admission (Killip class II or III). A total of 36,303 of 190,518 patients with AMI (19.1%) had CHF on admission; 70.6% were in Killip class II and 29.4% were in Killip class III. Patients who presented with CHF were less likely to receive fibrinolytic therapy or undergo primary PTCA. CHF on admission was a strong independent predictor of in-hospital death (adjusted odds ratio 1.68; 95% CI 1.62 to 1.75).

Hasdai and associates³⁸⁵ combined the data from four large randomized trials of fibrinolytic therapy for STEMI to describe the incidence, timing, and consequences of mild to moderate CHF in patients with STEMI. Excluding patients with cardiogenic shock, 17,949 of 61,041 (29.4%) patients had mild to moderate CHF. Among the cohort with mild to moderate CHF, 8.7% had CHF only at baseline, 57.6% had CHF only after admission, and 33.7% had CHF at baseline and after admission. The incidence of death was similar for patients without CHF and patients with CHF at baseline that resolved after admission. Patients with CHF that persisted from baseline or developed after admission had a four times greater risk of death at 30 days (8% versus 2%).

There is evidence that patients with STEMI complicated by CHF benefit from early revascularization. Analysis of an

Israeli database compared the outcomes of 629 patients with STEMI who presented in Killip class II or III CHF.³⁸⁶ Mortality at 6 months was lower among patients who underwent PTCA or CABG surgery within 30 days compared with patients who were managed noninvasively (11.6% versus 27.4%; odds ratio 0.40; 95% CI 0.24 to 0.64; $p < 0.0001$). Analysis of the NRMI-2 registry suggested that the risk of in-hospital death was reduced more by primary PCI than by fibrinolytic therapy in patients with CHF.²⁸³ Thus, the ACC/AHA Practice Guidelines recommend primary PCI for patients with severe CHF or pulmonary edema (Killip class III) when the onset of symptoms is within 12 hours.²⁰ Primary PCI is considered reasonable (a Class IIa recommendation) for patients who present with severe CHF, persistent ischemic symptoms, or hemodynamic or electrical instability 12 to 24 hours after symptom onset.²⁰

It is important to recognize that CHF also is an important prognostic factor in patients with UA or NSTEMI.³⁸⁷ Among a cohort of 13,707 patients with a confirmed diagnosis of ACS without prior CHF or cardiogenic shock at the time of presentation to the hospital, CHF (Killip class II or III) was present at hospital admission in 1778 patients (13%), and CHF developed later during hospitalization in an additional 869 patients (6.3%).³⁸⁷ The incidence of CHF was similar in patients with STEMI (15.6%) or NSTEMI (15.7%) but less frequent in patients with UA (8.2%). CHF at the time of admission was associated with a fourfold increase in crude in-hospital mortality rates across all three ACS subsets. The cumulative 6-month mortality rate was greater among patients in whom CHF developed during hospitalization (25.3%) than among patients who had CHF at admission (20.7%) or patients who did not have CHF (5.9%).

ACE inhibitors, eplerenone, and β -adrenergic antagonists are believed to improve the long-term survival of patients with MI complicated by CHF.³⁸⁸ The AIRE study showed that ramipril, initiated 3 to 10 days after acute MI, reduced all-cause mortality by 27% in patients with either STEMI or NSTEMI and clinical or radiologic evidence of CHF.³¹⁷ The EPHEsus study randomized patients with either STEMI or NSTEMI and left ventricular EF less than 40%, to eplerenone or placebo beginning 3 to 14 days after the acute MI.³²⁶ Ninety percent of the patients had CHF, documented by the presence of pulmonary rales, a third heart sound, or evidence of pulmonary venous congestion on the chest radiograph. Concomitant medications included β -blockers in 75% of patients and an ACE inhibitor or angiotensin receptor blocker in 86%. At 30 days after randomization, eplerenone reduced the risk of all-cause mortality by 31% (3.2% versus 4.6%; RR 0.69; 95% CI 0.54 to 0.89; $p = 0.004$).³⁸⁹ During a mean follow-up period of 16 months, the all-cause mortality rate was 14.4% in the eplerenone group and 16.7% in the placebo group (RR 0.85; 95% CI 0.75 to 0.96; $p = 0.008$).³²⁶

BHAT, a study that randomized patients to receive propranolol or placebo 5 to 21 days after acute MI, included 710 patients who had a history of CHF before enrollment.³⁹⁰ After an average follow-up period of 25 months, propranolol reduced total mortality by 27% and sudden death by 47%. A retrospective analysis of the AIRE study was performed to determine the effects of β -blockade on the outcomes for patients with acute MI complicated by CHF.³⁹¹ β -Blocker treatment was an independent predictor of

reduced risk of total mortality (hazard ratio 0.66; 95% CI 0.48 to 0.90). The CAPRICORN study showed that carvedilol, started 3 to 21 days after MI, reduced all-cause mortality by 33% in patients with a left ventricular EF of 40% or less.³¹² Unfortunately, patients with acute MI complicated by CHF are less likely to receive a β -blocker than are patients without CHF.³⁹²

On the basis of the foregoing evidence, the ACC/AHA Practice Guidelines include eight Class I recommendations for patients with STEMI complicated by pulmonary congestion²⁰: (1) an arterial oxygen saturation greater than 90% should be maintained using supplemental oxygen. (2) Morphine sulfate should be given. (3) Patients with a systolic blood pressure 100 mm Hg or higher should receive an ACE inhibitor, beginning with titration of a low dose of a short-acting drug such as captopril. (4) Patients with a systolic blood pressure of 100 mm Hg or higher should receive nitrates. (5) A loop diuretic should be administered to patients with volume overload. (6) Although β -blockade should be initiated before hospital discharge, β -blockers should not be administered acutely to patients with “frank cardiac failure evidenced by pulmonary congestion or signs of a low-output state.” (7) Patients already receiving an ACE inhibitor who have a left ventricular EF less than 40% and either symptomatic CHF or diabetes should receive long-term aldosterone blockade unless hyperkalemia (serum potassium greater than 5 mEq/L) or significant renal dysfunction (serum creatinine greater than 2.5 mg/dL in men or greater than 2 mg/dL in women) is present. (8) Echocardiography should be performed urgently to evaluate left and right ventricular function and to exclude a mechanical complication.

In view of the fact that the relevant clinical trials included patients with both STEMI and NSTEMI, it is logical that treatment of NSTEMI patients with CHF should conform to the practice guidelines as discussed for STEMI patients with CHF. Figure 30.7 presents an algorithm for the emergency management of MI complicated by CHF or hypotension.

RIGHT VENTRICULAR DYSFUNCTION AND INFARCTION

Among 416 patients with acute MI who were enrolled in an echocardiographic substudy of the SAVE trial, right ventricular function was an independent predictor of mortality and the development of CHF.³⁹³ The odds of cardiovascular mortality increased 16% for each 5% decrease in the percentage change in right ventricular cavity area from end diastole to end systole.

Occlusion of the right coronary artery (RCA) proximal to the acute marginal branches is the most frequent cause of right ventricular infarction, but occlusion of the LAD or a dominant left circumflex coronary artery also may result in right ventricular MI. Although autopsy studies have shown that anterior MI may be associated with a right ventricular infarction, right ventricular MI that is associated with hemodynamic compromise most commonly occurs in patients with an inferior MI because perfusion of the right ventricle occurs predominantly via the right ventricular branches of the RCA.^{394,395} In a series of 125 patients with acute inferior MI who underwent emergency coronary angiography, echocardiography performed before coronary reperfusion demonstrated ischemic dysfunction of the right

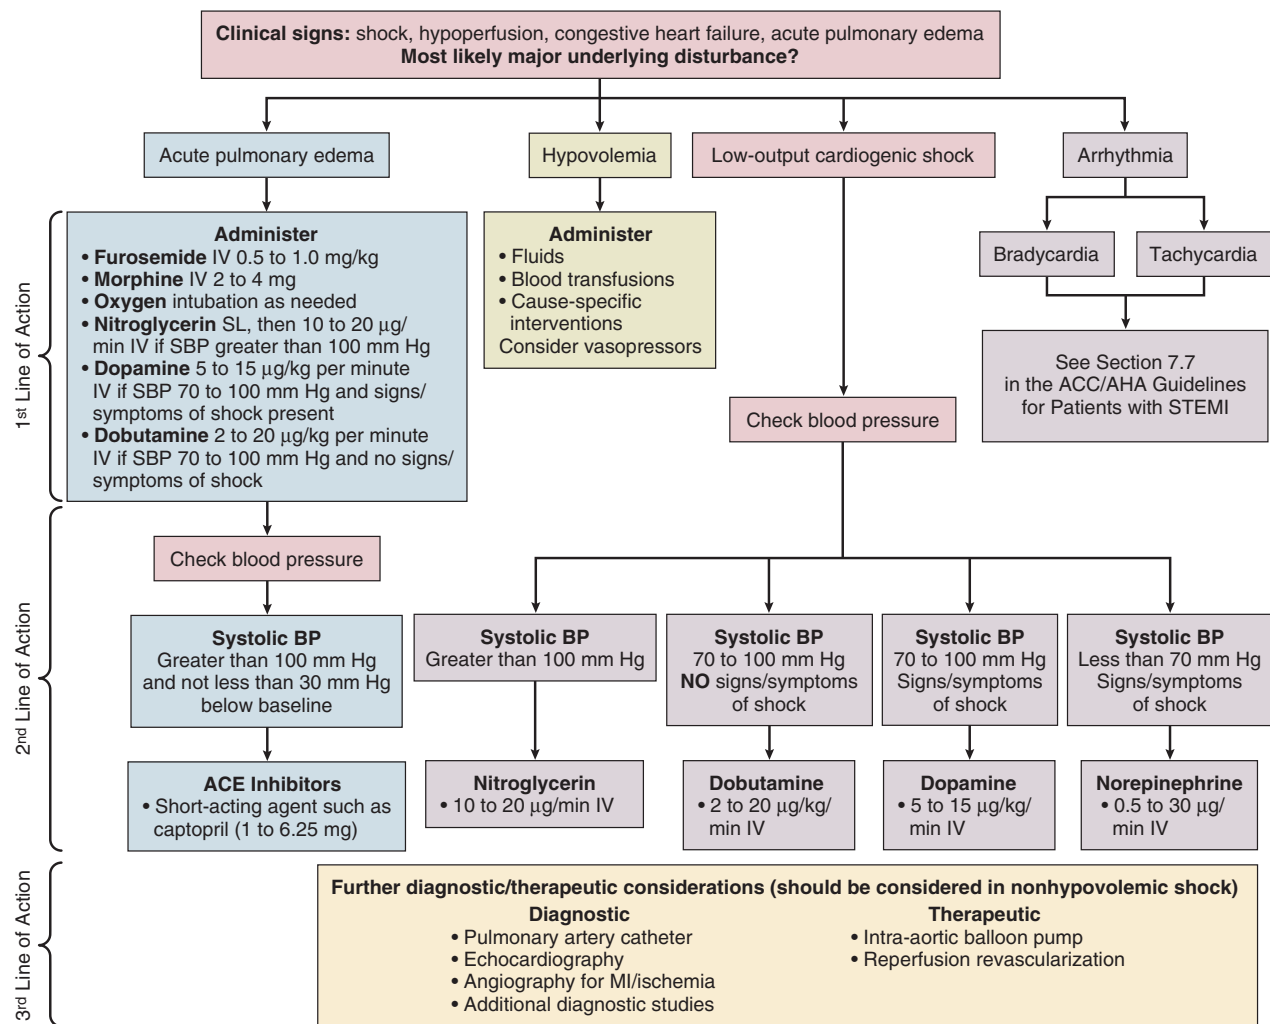

Figure 30.7 Algorithm for emergency management of complicated myocardial infarction (MI). ACE, angiotensin-converting enzyme; BP, blood pressure; IV, intravenous; SBP, systolic BP; SL, sublingual; STEMI, ST segment elevation myocardial infarction. (Data from Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care: Part 7, the era of reperfusion: Section 1, acute coronary syndromes (acute myocardial infarction). Circulation 2000;102[Suppl I]:I-172-I-203.)

ventricle in 53 (42%) patients.³⁹⁶ The RCA was the IRA in all patients with right ventricular MI, and depressed flow in the right ventricular branches was evident in each case. Right ventricular branch flow was preserved in patients without right ventricular MI.

Patients with inferior MI complicated by right ventricular infarction have an increased risk of major complications, including death, cardiogenic shock, and ventricular arrhythmias.³⁹⁷ Cardiogenic shock during hospitalization occurred in 6.9% of a series of 491 patients with inferior MI complicated by right ventricular MI.³⁹⁷ Patients with right ventricular infarction complicated by cardiogenic shock do not have a better prognosis than patients with cardiogenic shock associated with left ventricular failure.³⁹⁸ Among a cohort of 1129 patients with acute inferior MI, there was no difference in left ventricular infarct size or function between patients with (n = 491) and patients without (n = 638) right ventricular MI, indicating that the increased risk of right ventricular MI is due to right ventricular dysfunction rather than greater left ventricular injury.³⁹⁷ The impact of right ventricular MI on prognosis may depend on the patient's age.³⁹⁹ Among a series of 798 consecutive patients with acute

inferior MI, 296 (37%) satisfied electrocardiographic or echocardiographic criteria for right ventricular infarction.³⁹⁹ Major complications (45% versus 19%, $p < 0.0001$) and in-hospital death (22% versus 6%, $p < 0.0001$) occurred more often in patients with than in those without right ventricular MI. The diagnosis of right ventricular MI increased the mortality risk in patients aged 65 or greater, but not among younger patients.

Although numerous electrocardiographic signs of right ventricular MI have been described, ST segment elevation in lead V_4R is the most reliable electrocardiographic indicator of this form of MI.⁴⁰⁰ Zehender and associates⁴⁰¹ studied the diagnostic and prognostic value of ST segment elevation in V_4R in a series of 200 consecutive patients with acute inferior MI. ST segment elevation in lead V_4R was present on the initial ECG in 107 patients (54%). Based on the results of autopsy, coronary angiography, right ventriculography, nuclear scan, or invasive hemodynamic data, ST segment elevation in V_4R had 88% sensitivity, 78% specificity, and 83% diagnostic accuracy for right ventricular MI. ST segment elevation in V_4R was associated with an in-hospital mortality of 31%, compared with 6% among patients without

ST segment elevation in V_4R ($p < 0.001$). Multivariate analysis of clinical data confirmed that 0.1 mV or greater of ST segment elevation in V_4R was a strong independent predictor of in-hospital death (RR 7.7; 95% CI 2.6 to 23) and major complications (RR 4.7; 95% CI 2.4 to 9).

The triad of hypotension, clear lung fields, and elevated jugular venous pressure should raise a suspicion of right ventricular MI in patients with inferior STEMI, but the triad has a sensitivity of less than 25%.⁴⁰² The hemodynamic criteria that have been used to diagnose right ventricular MI are right atrial pressure greater than 10 mm Hg and equal or nearly equal to the pulmonary capillary wedge pressure, or a noncompliant pattern in the right atrium.⁴⁰³ According to the ACC/AHA Practice Guidelines for STEMI, inferior STEMI with hemodynamic compromise is a Class I indication for recording lead V_4R and an echocardiogram to screen for right ventricular MI.²⁰ Echocardiographic signs of this disorder include right ventricular dilation, right ventricular asynergy, and abnormal interventricular septal motion.⁴⁰³ Echocardiography also is valuable to exclude pericardial tamponade because both right ventricular MI and pericardial tamponade may manifest with hypotension and elevated jugular venous pressure.⁴⁰⁴

The ACC/AHA guidelines emphasize the importance of maintenance of right ventricular preload, reduction of right ventricular afterload, inotropic support of the right ventricle, maintenance of atrioventricular synchrony, and early reperfusion of the IRA.²⁰ Volume loading plus dobutamine, but not volume loading alone, has been shown to improve cardiac index in patients with acute right ventricular infarction.⁴⁰⁵ Systemic vasodilators are poorly tolerated, and hypotension after administration of sublingual nitroglycerin is a common event in patients with right ventricular MI. Short-term inhalation of nitric oxide, a selective vasodilator of the pulmonary circulation, improved cardiac index by 24% in a series of 13 patients with right ventricular infarction and cardiogenic shock.⁴⁰⁶ In patients with right ventricular MI complicated by cardiogenic shock and refractory low cardiac output and hypotension, insertion of a percutaneous ventricular assist device should be considered as a therapeutic option.⁴⁰⁷

The status of right atrial function is an important determinant of the hemodynamic consequences of right ventricular MI.⁴⁰⁸ Hemodynamic compromise may result if the atrial contribution to ventricular filling is lost in patients with right ventricular MI. Therefore, high-grade atrioventricular block, other bradyarrhythmias, and atrial fibrillation are common causes of hypotension in patients with right ventricular MI. Ventricular pacing may not increase cardiac output in such patients, although atrial pacing and atrioventricular sequential pacing have been shown to improve cardiac output.^{409,410} Atrial fibrillation associated with hemodynamic compromise is an indication for electrical cardioversion.

The elevated right atrial pressure in patients with right ventricular MI may cause refractory hypoxemia as a result of increased right-to-left shunting in patients with an atrial septal defect or patent foramen ovale.^{406,411} Inhalation of NO reduced right-to-left shunting by 56% in a series of three patients with right ventricular MI.⁴⁰⁶ Right-to-left shunting in patients with right ventricular MI also can be treated by percutaneous closure of the patent foramen ovale.⁴¹¹

Some evidence indicates that reperfusion of the IRA improves right ventricular function and clinical outcome in patients with MI. Successful PCI of an occluded RCA in patients with right ventricular infarction has been associated with improved right ventricular wall motion within 1 hour⁴¹² and a reduction in right atrial pressure within 8 hours.⁴¹³ Three to 5 days after successful PCI, right ventricular function was normal in 95% of patients.⁴¹² In a study of the data for 49 patients with shock and right ventricular MI who were enrolled in the SHOCK trial registry, the in-hospital mortality rate was found to be 65.2% among patients who did not undergo revascularization, compared with 42.3% among patients who underwent PCI or CABG surgery.³⁹⁸

MECHANICAL CAUSES OF CONGESTIVE HEART FAILURE OR LOW CARDIAC OUTPUT

Mitral Regurgitation

Among 1976 patients with acute MI who were not in cardiogenic shock and underwent cardiac catheterization within 12 hours of symptom onset, left ventriculography demonstrated mild mitral regurgitation in 192 patients (9.7%) and moderate or severe mitral regurgitation in 58 patients (2.9%).⁶¹ By multivariate analysis, mild mitral regurgitation and moderate or severe mitral regurgitation were the two strongest independent predictors of 1-year mortality. The hazard ratios were 2.40 (95% CI 1.31 to 4.42; $p = 0.005$) for mild and 2.82 (95% CI 1.34 to 5.92; $p = 0.006$) for moderate or severe mitral regurgitation. The 1-year mortality rates were 2.9% for patients with no mitral regurgitation ($n = 1726$), 8.5% for patients with mild mitral regurgitation ($n = 192$), and 20.8% for patients with moderate or severe mitral regurgitation ($n = 58$).

Acute severe mitral regurgitation accounted for 6.9% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or the randomized trial.³⁶⁹ The median time from the onset of MI to shock was 12.8 hours.⁴¹⁴ In a postmortem series of 20 cases of papillary muscle rupture, the posteromedial papillary muscle was ruptured in 16 patients and the anterolateral papillary muscle was ruptured in four patients.⁴¹⁵ The greater tendency of the posteromedial papillary muscle to rupture is reflected by the distribution of the IRA in a series of 98 patients with acute mitral regurgitation and cardiogenic shock who were enrolled in the SHOCK studies. The location of the index MI was anterior in 34% of patients and nonanterior in 66%.⁴¹⁴

The diagnosis of acute severe mitral regurgitation should be suspected in patients with acute onset of pulmonary edema or hypotension. The absence of a loud murmur does not exclude severe mitral regurgitation. The diagnosis can be confirmed by transthoracic or transesophageal echocardiography. The treatment of acute severe mitral regurgitation should include inotropic support, afterload reduction, an IABP, and emergency mitral valve surgery, but mortality is high despite surgical treatment. Among the patients with acute severe mitral regurgitation and cardiogenic shock who were enrolled in the SHOCK registry or the randomized trial, the in-hospital mortality rate was 40% among 43 patients who underwent valve surgery, compared with 71% among 51 patients who did not.⁴¹⁴

Ventricular Septal Rupture

Among 41,021 patients with STEMI who were enrolled in the GUSTO-I trial, the incidence of ventricular septal rupture was only 0.2% (84/41,021 patients).⁴¹⁶ Acute ventricular septal rupture accounted for 3.9% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or randomized trial.³⁶⁹

The clinical manifestations of ventricular septal rupture may include chest pain, dyspnea, and hypotension. A harsh holosystolic murmur may be audible. Cardiogenic shock occurred in 67% of patients in the GUSTO-I trial in whom ventricular septal rupture developed.⁴¹⁶ The diagnosis of ventricular septal rupture can be confirmed by Doppler echocardiography or right heart catheterization to measure the oxygen saturation in the right atrium, right ventricle, and pulmonary artery. The median time from MI to diagnosis of ventricular septal rupture was 16 hours among a series of patients with ventricular septal rupture and cardiogenic shock.⁴¹⁷ The electrocardiographic location of the MI was inferior in 26 patients, anterior in 22, both anterior and inferior in 3, and apico-lateral in 1 patient.⁴¹⁷ Only 35 of 55 patients underwent coronary angiography, and the IRA was identified in only 26 patients: the RCA in 12, the LAD in 11, and the left circumflex coronary artery in 3 cases.

The location of the IRA may be an important determinant of survival in patients with ventricular septal rupture.^{416,418} Among a series of 25 patients with this diagnosis, mortality was greater among patients with inferior MI than among patients with anterior MI.⁴¹⁸ At least two factors may explain the differential outcome of patients with inferior and anterior MI complicated by ventricular septal rupture. First, the right ventricular volume overload caused by the left-to-right shunt may be less tolerated in the presence of ischemia or infarction of the right ventricle, both of which are more common with an inferior MI than an anterior MI. Second, histopathologic studies have shown that complex septal defects that are more difficult to repair surgically are more common in patients with an inferior MI.⁴¹⁹

An IABP has been shown to decrease the shunt and increase systemic cardiac output in patients with ventricular septal rupture.⁴²⁰ Therefore, vasodilator therapy and an IABP often are used to stabilize patients before surgical repair of the rupture. The overall in-hospital survival rate among patients with ventricular septal rupture in the SHOCK registry was only 13% (7/55).⁴¹⁷ Although six of the seven survivors underwent surgical repair, mortality was 81% (25/31) in the group of patients who underwent surgery. In the GUSTO-I trial, patients whose rupture was repaired surgically had better 30-day mortality (47%) than patients who received medical treatment (94%).⁴¹⁶ Percutaneous closure of acute ventricular septal rupture may be an option in the future.

Left Ventricular Free Wall Rupture

Rupture of the left ventricular free wall may manifest in any of several ways: pericardial tamponade with acute hemodynamic collapse and immediate death, gradual onset of tamponade and hypotension, or subacute formation of a pseudoaneurysm.⁴²¹ Although a 6% rate of cardiac rupture among patients with acute MI often is quoted, reports

suggest that the rate probably is lower, at least among patients who receive reperfusion therapy. A total of 65 (1.7%) cases of cardiac rupture occurred among 3759 patients with STEMI who received fibrinolytic therapy and were randomized to receive either adjunctive heparin or hirudin.⁴²² The prevalence of cardiac rupture or pericardial tamponade was 2.3% (28/1190) among patients with cardiogenic shock in the SHOCK registry; 13 patients had both rupture and pericardial tamponade, 9 had tamponade alone, and 6 had rupture alone.⁴²³

It has been suggested that the incidence of cardiac rupture may be lower after primary PCI than after fibrinolytic therapy. The overall incidence of left ventricular free wall rupture was 2.5% (n = 34) among 1375 patients with STEMI who underwent primary PCI (55.4%) or fibrinolytic therapy (44.6%).⁴²⁴ In a multivariate analysis, primary PCI was independently associated with a lower incidence of rupture, but no significant difference was observed in the incidence of rupture after primary PCI or fibrinolytic therapy (1.8% versus 3.3%; $p = 0.686$).

The timing of reperfusion therapy may affect both the risk and the timing of free wall rupture. Death from cardiac rupture appears to occur earlier in patients given fibrinolytic therapy than among patients who do not undergo reperfusion therapy.⁴²⁵ Honan and associates⁴²⁶ analyzed the relationship between the risk of cardiac rupture and the timing of fibrinolytic therapy for 58 cases of cardiac rupture among 1638 patients who were enrolled in four randomized trials that compared intravenous streptokinase with no fibrinolytic therapy (in the control group). The odds ratio of cardiac rupture increased significantly with increasing delay in the time to treatment. Regression analysis suggested that treatment within 7 hours after symptom onset reduces the risk of cardiac rupture, whereas treatment later than 17 hours after symptom onset increases the risk of cardiac rupture.⁴²⁶ Thus, it was hypothesized that early fibrinolytic therapy reduces the risk of rupture by reducing the extent of myocardial necrosis, whereas late fibrinolytic therapy increases the risk of rupture by promoting hemorrhagic infarction.

The antemortem diagnosis of free wall rupture, pericardial tamponade, and left ventricular pseudoaneurysm usually is confirmed by an echocardiogram. An echocardiogram was obtained in 20 of the 28 patients in the SHOCK registry who had rupture or pericardial tamponade. A pericardial effusion was observed in 15 (75%) and a myocardial tear was detected in 39%.⁴²³ Six patients underwent pericardiocentesis alone, and 21 had surgical repair of the rupture. The in-hospital survival rate was 39.3%.

CARDIAC ARRHYTHMIAS AND HEART BLOCK

Both atrial and ventricular arrhythmias are common in patients with acute MI. The incidence of atrial fibrillation was 10.4% among 40,891 patients who were enrolled in the GUSTO-I trial.³²⁷ Among patients enrolled in the TRACE study, which enrolled patients with an acute MI and a left ventricular EF less than 35%, atrial fibrillation occurred in 21% of patients and was associated with a 50% increase in the adjusted mortality.³²⁸ Management of atrial arrhythmias is discussed in another chapter.

The likelihood of primary ventricular fibrillation (occurring within 48 hours of acute MI and in the absence of

cardiogenic shock or severe CHF) is not altered by fibrinolytic therapy, with an incidence of ventricular fibrillation during the first hospital day of 2.99% for both the fibrinolytic and placebo groups.³³¹ Some evidence, however, suggests that fibrinolytic therapy exerts a protective effect against secondary ventricular fibrillation (occurring in patients with acute MI complicated by CHF or shock).^{331,332} Management of ventricular arrhythmias is discussed in Chapter 32.

The incidence of second-degree or third-degree AV block was 6.9% among 75,993 patients with STEMI who received fibrinolytic therapy and were enrolled in a database that combined four randomized clinical trials.⁴²⁷ Inferior MI was the strongest independent predictor of AV block (odds ratio 3.3; 95% CI 3.1 to 3.5). In comparison with patients without AV block, adjusted mortality was greater at 30 days, 6 months, and 1 year among patients with AV block. The adjusted mortality odds ratios at 1 year were 2.4 (95% CI 2.2 to 2.6) for patients with AV block and inferior MI and 3.3 (95% CI 3.0 to 3.7) for patients with AV block and anterior MI.

UNSTABLE AND NON-ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

CLINICAL MANIFESTATIONS

DEFINITION

The ACC/AHA Practice Guidelines define *UA* as “an acute process of myocardial ischemia that is not of sufficient severity and duration to result in myocardial necrosis.”¹ *NSTEMI* is defined as “an acute process of myocardial ischemia with sufficient severity and duration to result in myocardial necrosis.”¹ Thus, *NSTEMI* is distinguished from *UA* by the detection of cardiac markers indicative of myocardial necrosis, such as troponin I or T, in patients with *NSTEMI*.

CLINICAL HISTORY

Criteria for the diagnosis of *UA* are based on the Canadian Cardiovascular Society (CCS) grading system⁴²⁸ (Table 30.3). The three principal presentations of *UA* are angina that occurs at rest, new-onset CCS class III or IV angina, and angina that has increased from class I or II to class III or IV.⁴²⁹

The GRACE registry analyzed the presenting symptoms of 20,881 patients with STEMI, *NSTEMI*, or *UA*.¹⁵ Among the patients with *UA* and *NSTEMI*, 5.7% and 12.3%, respectively, presented with symptoms other than chest pain. Patients with *UA* or *NSTEMI* who presented with atypical symptoms were less likely to undergo coronary angiography, PCI, or CABG surgery and were less likely to receive heparin, aspirin, or β -blockers. The absence of chest pain among patients with ACS was predictive of an increased risk of in-hospital death.

Several risk-stratification models have been developed to evaluate patients with suspected ACS. The TIMI risk score utilizes seven variables to calculate a score that is predictive of the risk of death and ischemic events in patients with suspected ACS.⁴³⁰ Four of the seven variables are derived from the clinical history: age 65 years or older, at least three risk factors for CAD (family history of CAD, hypertension, hypercholesterolemia, diabetes, cigarette smoking), two or

Table 30.3 Grading of Angina Pectoris According to Canadian Cardiovascular Society Classification

Class	Description of Stage
I	“Ordinary physical activity does not cause . . . angina,” such as walking or climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
II	“Slight limitation of ordinary activity.” Angina occurs on walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals; in cold, in wind, or under emotional stress; or only during the few hours after awakening. Angina occurs on walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and under normal conditions.
III	“Marked limitations of ordinary physical activity.” Angina occurs on walking one to two blocks on the level and climbing one flight of stairs under normal conditions and at a normal pace.
IV	“Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest.”

Modified from Campeau L: Grading of angina pectoris. Circulation 1976;54:522-523 (Letter).

more anginal events within the previous 24 hours, and use of aspirin within the previous 7 days.⁴³⁰ The GRACE risk score and a PURSUIT risk model also have been shown to have predictive power in patients with suspected ACS.^{431,432}

PHYSICAL EXAMINATION

As in patients with STEMI, evidence of heart failure at the time of initial presentation has prognostic importance in patients with non-ST segment elevation ACS. In a database accrued from studies in 26,090 patients with *UA* or *NSTEMI*, heart rate, systolic blood pressure, and Killip class were independent predictors of mortality at 30 days and 6 months.⁴³³ Patients in Killip class II, III, or IV constituted only 11% of the population but accounted for 30% of the deaths.

DIAGNOSTIC APPROACH

ELECTROCARDIOGRAM

The admission ECG has prognostic value in patients with ACS.^{434,435} Although normal or nonspecific findings on the initial ECG confer a better prognosis than ST segment depression or elevation seen on the ECG, such findings do not predict a benign outcome in patients with suspected ACS.⁴³⁵ The risk of death or reinfarction at 30 days or 6 months is similar in patients with ST segment elevation and in those with ST segment depression; the risk is lower among patients with isolated T wave inversion.⁴³⁴ The GUSTO-IIb clinical trial enrolled 12,142 patients with symptoms of cardiac ischemia at rest and electrocardiographic signs of myocardial ischemia.⁴³⁴ After adjustment for factors

associated with an increased risk of death or reinfarction, the odds of death or reinfarction at 30 days were 1.68 (95% CI 1.36 to 2.08) in those with ST segment elevation and 1.62 (95% CI 1.32 to 1.98) in those with ST segment depression compared with those who had T wave inversion only on the admission ECG.⁴³⁴

The impact of invasive management on outcome in patients with ACS is predicted by the presence or absence of ST segment depression on the admission ECG. Among patients with ACS who were enrolled in the Fast Revascularization during InStability in Coronary Artery Disease (FRISC II) randomized trial comparing early invasive management and a noninvasive strategy, ST segment depression was present at enrollment in 45.5% of patients.⁴³⁶ Among the patients who presented with ST segment depression, the invasive strategy reduced the risk of death or MI at 12 months from 18.2% to 12% (RR 0.66; 95% CI 0.50 to 0.88; $p = 0.004$). Mortality was reduced from 5.8% to 3.3% (RR 0.58; 95% CI 0.33 to 1.01; $p = 0.050$). Among the patients without ST segment depression, the corresponding rates of death or MI were 10.4% and 8.9% ($p = 0.36$), and the mortality rates were 2% and 1.2% ($p = 0.26$). A similar dichotomy was found in the Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)-TIMI 18 randomized trial of early invasive versus conservative strategies in patients with ACS.⁴³⁷ Thus, according to the ACA/AHA Practice Guidelines for the management of patients with UA and NSTEMI, new or presumably new ST segment depression is a Class I indication for use of an invasive strategy.¹

The magnitude^{438,439} and the location⁴⁴⁰ of ST segment depression also provide independent prognostic information in patients with UA and NSTEMI. Among 1846 patients who were enrolled in the TACTICS—TIMI 18 trial, the magnitude of ST segment depression was a predictor of unsuccessful medical therapy in patients who were randomized to the conservative strategy.⁴³⁹ The magnitude of ST segment depression was an independent predictor of the extent of CAD among patients who were randomized to the early invasive strategy. After adjustment for baseline characteristics and the degree of troponin elevation, the benefit of an early invasive strategy was greater among patients with ST segment depression of 0.10 mV or greater, compared with patients with 0.05 to 0.09 mV of ST segment depression.

Among a cohort of 432 patients with a first NSTEMI, patients with ST segment depression in two or more lateral leads (I, aVL, V₅, or V₆) had lower left ventricular EFs, more frequent left main coronary artery or three-vessel CAD, and greater in-hospital mortality.⁴⁴⁰ Although isolated T wave inversion on the admission ECG is associated with a better prognosis than ST segment depression or elevation, negative T waves in leads V₂ and V₃ are associated with critical stenosis of the proximal LAD and stunning of the myocardium supplied by the LAD.^{441,442}

BIOCHEMICAL MARKERS

Biochemical markers such as troponin or CK-MB provide both diagnostic and prognostic information. As discussed, the distinction between NSTEMI and UA is based on the blood assays for biochemical markers of myocardial necrosis. Among 1404 patients with UA or NSTEMI who were

enrolled in the TIMI IIIB trial, the mortality rate at 42 days was 3.7% (21/573) for patients with a baseline troponin I 0.4 ng/mL or greater, compared with 1% (8/831) for patients with a troponin I less than 0.4 ng/mL ($p < 0.001$).⁴⁴³ There were significant increases in mortality with increasing levels of troponin I. An elevated troponin in patients with suspected ACS confers a greater risk of death or reinfarction even among patients without significant angiographic CAD.⁴⁴⁴ Patients with ACS who have an elevated troponin, even if the elevation is minor, derive greater benefit from platelet GP IIb/IIIa inhibitors^{445,446} or invasive management⁴⁴⁷ than do patients without an elevated troponin.

Another biochemical marker that provides prognostic information is brain natriuretic peptide (BNP). An elevated BNP at the time of presentation or after hospital discharge in patients with ACS is an independent predictor of death or new-onset CHF during follow-up.^{448,449}

CORONARY CT ANGIOGRAPHY

Several randomized trials have been performed to evaluate the utility of coronary CT angiography (CCTA) in “low-risk” patients with chest pain. Sixteen emergency departments enrolled 749 patients in a multicenter, randomized study called the Coronary Computed Tomographic Angiography for Systematic Triage of Acute Chest Pain Patients to Treatment (CT-STAT) trial.⁴⁵⁰ The patients were randomized to either CCTA ($n = 361$) or rest-stress myocardial perfusion imaging (MPI) ($n = 338$). The time to diagnosis and costs of care were less in the patients who were randomized to CCTA.⁴⁵⁰ A larger study randomized low to intermediate-risk patients with possible ACS, in a 2:1 ratio, to undergo CCTA or traditional care.⁴⁵¹ None of the 640 patients with a negative CCTA died or had an MI within 30 days.⁴⁵¹ A multicenter trial that randomized 1000 patients with suspected ACS but no ischemic electrocardiographic changes and a normal initial serum troponin found that patients evaluated by CCTA were discharged sooner than patients who underwent standard evaluation.⁴⁵² The patients who were randomized to CCTA, however, underwent more downstream testing and had greater radiation exposure.⁴⁵² The 2011 ACCF/AHA Focused Update of the Guidelines for the Management of Patients with UA or NSTEMI included a Class IIa recommendation that “In patients with suspected ACS with a low or intermediate probability of CAD, in whom the follow-up 12-lead ECG and cardiac biomarkers measurements are normal, performance of a noninvasive coronary imaging test (i.e., CCTA) is reasonable as an alternative to stress testing.”¹

APPROACH TO MANAGEMENT

Figure 30.8 presents an algorithm for the treatment of UA and non-ST segment elevation myocardial infarction. Specific components of management are discussed next.

ANTI-ISCHEMIC THERAPY

Nitrates

The Class I recommendations for anti-ischemic therapy in patients with UA or NSTEMI include nitroglycerin administered initially as a sublingual tablet or spray, followed by intravenous infusion. Although nitroglycerin often relieves

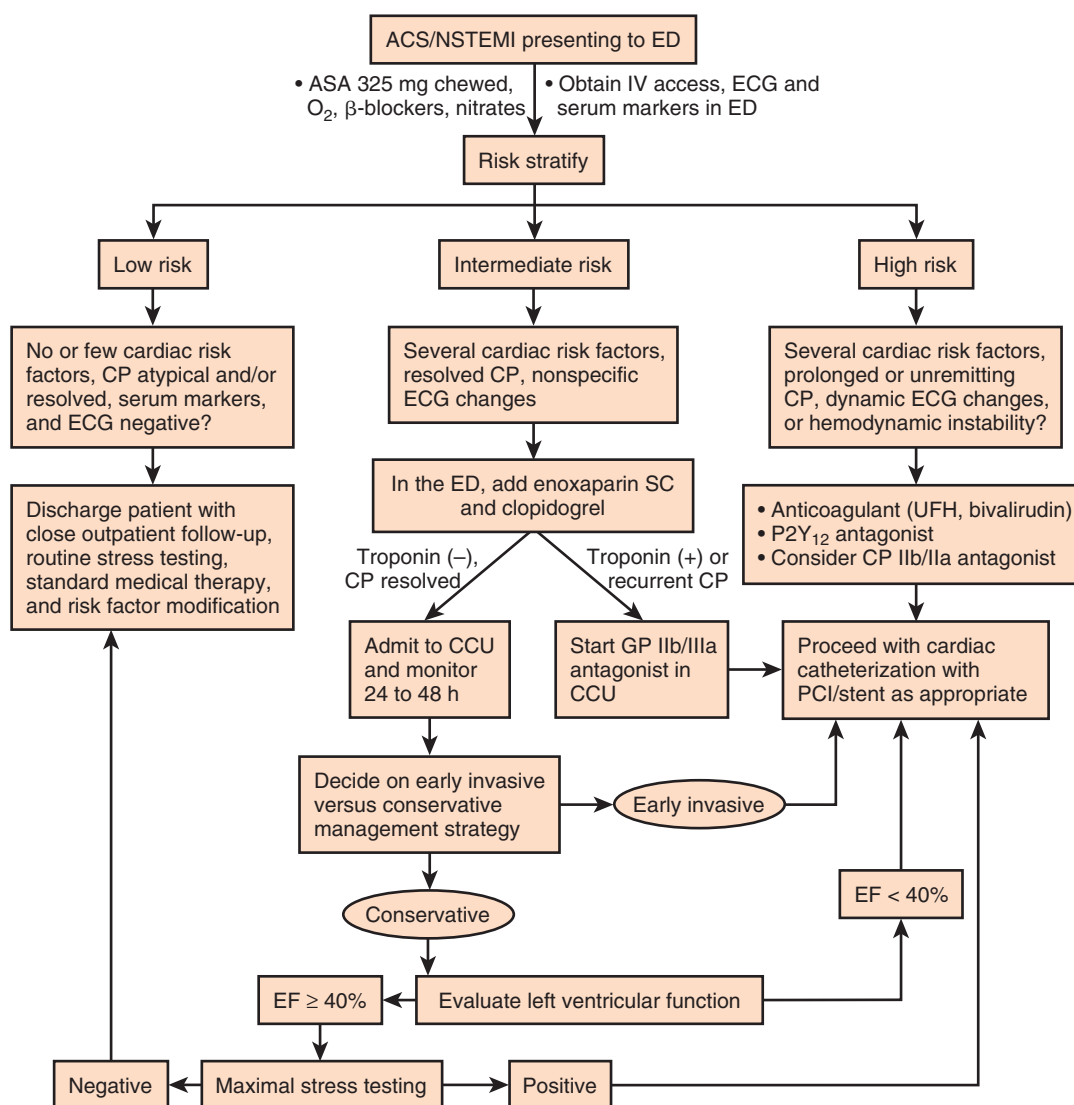

Figure 30.8 Algorithm for the treatment of unstable angina or non-ST segment elevation myocardial infarction. *Note:* Enoxaparin is not recommended for use in patients with known bleeding disorders or significant renal insufficiency (serum creatinine of 2 to 2.5 mg/dL or greater). ACS, acute coronary syndrome; ASA, acetylsalicylic acid (aspirin); CCU, critical care unit; CP, chest pain; ECG, electrocardiogram; ED, emergency department; EF, ejection fraction; IV, intravenous; NSTEMI, non-ST segment elevation myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty; SC, subcutaneous. (From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction]. *Circulation* 2004;110:e82-e292.)

chest pain in patients with ACS, nitrates have not been shown to reduce clinical events in patients with UA or NSTEMI. Abrupt cessation of intravenous nitroglycerin may be associated with rebound myocardial ischemia in patients with ACS.⁴⁵³ After intravenous infusion of nitroglycerin for longer than 24 hours the development of tolerance may require an increase in the dose to maintain efficacy, but 200 µg/min usually is considered the maximum dose.

β-Blockers

The Class I recommendations for anti-ischemic therapy in patients with UA or NSTEMI include the administration of a β-blocker within the first 24 hours for patients who do not have signs of heart failure, evidence of a low output state, increased risk for cardiogenic shock, or other

relative contraindications to β-blockade. Nevertheless, many patients who are eligible for a β-blocker therapy do not receive it, possibly because there are limited data regarding the efficacy of β-blockers in patients with UA or NSTEMI.⁴⁵⁴ Clinical trials that evaluated β-blockers in patients with UA were not adequately powered to demonstrate reductions in mortality. A pooled analysis of randomized trials in patients with threatened or evolving MI concluded that β-blockers reduce the risk of MI by 13%.⁴⁵⁵ A report from the GRACE registry analyzed the outcomes of 7106 patients with NSTEMI.⁴⁵⁴ β-Blocker therapy was initiated within 24 hours of admission in 76% of patients without contraindications. After multivariable logistic regression analysis to adjust for presence of comorbidity, both in-hospital mortality (odds ratio 0.58; 95% CI 0.42 to

0.81) and 6-month mortality (OR 0.75; 95% CI 0.56 to 0.997) were lower among patients who received β -blockers than among patients who did not.

Calcium Antagonists

The Holland Interuniversity Nifedipine/Metoprolol Trial (HINT) found that nifedipine alone increased the risk of MI or recurrent angina, relative to placebo, by 24% in patients with UA.⁴⁵⁶ Therefore, the ACC/AHA Practice Guidelines for UA and NSTEMI include a Class III recommendation for immediate-release dihydropyridine calcium antagonists in the absence of a β -blocker.

The Multicenter Diltiazem Postinfarction Trial (MDPIT) randomized 2466 patients to receive diltiazem or placebo 3 to 15 days after acute MI.³⁴⁶ Approximately 70% of patients met ECG criteria for a Q wave MI, and 25% had non-Q wave MI. The percentage of patients with STEMI or NSTEMI was not reported. Total mortality rates for the two treatment groups were nearly identical, but treatment with diltiazem was associated with increased mortality in patients with either radiographic evidence of pulmonary congestion or a left ventricular EF less than 40%. Also, diltiazem was associated with an increased risk of late-onset CHF in patients with a left ventricular EF less than 40%.³⁴⁷

Gibson and colleagues⁴⁵⁷ performed a post hoc subset analysis of the 817 patients with non-Q wave MI and no pulmonary congestion who were enrolled in two clinical trials: MDPIT and the second Danish Verapamil Infarction Trial (DAVIT-II).⁴⁵⁷ The adjusted all-cause mortality was lower among patients who were given diltiazem or verapamil than among those who received placebo (RR 0.65; 95% CI 0.40 to 1.05). Nevertheless, calcium antagonists are not considered first-line therapeutic agents in patients with ACS and are reserved for patients with recurrent ischemia, but no severe left ventricular dysfunction, who have a contraindication to β -blockers.

Intra-aortic Balloon Counterpulsation

Intra-aortic balloon counterpulsation is believed to increase myocardial oxygen supply by increasing diastolic pressure and to reduce myocardial oxygen demand by afterload reduction of the left ventricle. The indications for an IABP in patients with ACS include refractory ischemia, hypotension, and cardiogenic shock, although this modality should be considered an adjunct to definitive therapies such as percutaneous or surgical myocardial revascularization.

ANTIPLATELET THERAPY

Aspirin

UA and NSTEMI are Class I indications for aspirin, which should be started as soon as possible and continued indefinitely. The recommendation is based on the results of four small randomized trials. A pooled analysis of the results concluded that aspirin reduces the risk of death or MI by 50% in patients with UA. The optimal dose of aspirin in patients with ACS is uncertain.⁴⁵⁸ An aspirin dose of 75 mg/day reduced the risk of MI or death after 1 year in patients with UA or non-Q wave MI who were enrolled in a prospective, randomized, double-blind, placebo-controlled multicenter trial (RR 0.52; 95% CI 0.37 to 0.72).⁴⁵⁹ Among 20,521 patients with ACS who were enrolled in the GUSTO IIb and

Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trials, an aspirin dose 150 mg or greater was associated with a lower risk of MI at 6 months, compared with an aspirin dose less than 150 mg (hazard ratio 0.79; 95% CI 0.64 to 0.98; $p = 0.03$).⁴⁶⁰ The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial randomized 12,562 patients with ACS to aspirin plus clopidogrel 75 mg daily or aspirin plus placebo.⁴⁶¹ The study protocol recommended an aspirin dose of 75 to 325 mg and the dose was left to the discretion of the local investigator. In both arms of the study higher doses of aspirin were associated with an increased risk of major bleeding but clinical event rates were not reduced by higher doses of aspirin. PCI-CURE was a substudy of the CURE trial that consisted of the 2658 patients who underwent PCI.^{462,463} A post hoc analysis of the patients who were enrolled in PCI-CURE found that the moderate-dose (101 to 199 mg) and high-dose (≥ 200 mg) aspirin groups had similar rates of cardiovascular death, MI, or stroke compared with the low-dose (≤ 100 mg) aspirin group, but high-dose aspirin was associated with an increased risk of major bleeding.^{462,463}

The Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events—Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) Trial was the first randomized trial to compare two different doses of aspirin in patients with ACS.^{464,465} The primary results have been published in two complementary papers in the September 2, 2010, issue of the *New England Journal of Medicine* (NEJM) and the October 9, 2010, issue of *Lancet*.^{464,465} The NEJM paper presents an analysis of the entire enrollment of 25,086 patients, including patients who did not undergo coronary angiography or PCI, whereas the *Lancet* paper describes a prespecified analysis of the 17,263 patients who underwent PCI. Among the entire cohort of 25,086 patients there was no significant difference between the higher dose of aspirin (300 to 325 mg daily) and the lower dose of aspirin (75 to 100 mg daily) with respect to the primary composite end point of cardiovascular death, myocardial infarction, or stroke at 30 days. Although the rates of major bleeding were 2.3% for both doses of aspirin, there was significantly less minor bleeding among the patients who received the lower dose of aspirin (4.4% versus 5%; hazard ratio 1.13; $p = 0.04$).

Based on an analysis of the PLATO trial, the label for ticagrelor, a platelet P2Y₁₂ receptor inhibitor, includes a “black box” warning that maintenance doses of aspirin reduce the effectiveness of ticagrelor. The most recent update of the practice guidelines for PCI includes a Class IIa recommendation that it is reasonable to prescribe a maintenance aspirin dose of 81 mg daily in preference to higher doses.⁹⁸

Inhibitors of the Platelet P2Y₁₂ Receptor

Inhibitors of the platelet P2Y₁₂ receptor have been shown to improve outcomes in patients with UA or NSTEMI.^{466,467} An open study that randomized patients with UA to ticlopidine or conventional therapy (excluding aspirin) demonstrated a 46% reduction in the risk of vascular death and nonfatal MI.⁴⁶⁶ Clopidogrel has a more rapid onset of action and a better safety profile than ticlopidine. The CURE trial demonstrated that the combination of clopidogrel and aspirin,

compared with aspirin alone, improved outcomes among patients with ACS without ST segment elevation.⁴⁶⁷

There is extensive evidence that platelet inhibition by clopidogrel is influenced by both drug interactions and certain genotypes that affect the metabolism of clopidogrel, a prodrug that is converted to an active metabolite by CYP2C19 activity, a hepatic cytochrome P450 enzyme.^{468,469} Co-administration of clopidogrel and drugs that are metabolized by CYP2C19, such as some proton pump inhibitors, may inhibit the formation of clopidogrel's active metabolite, resulting in diminished platelet inhibition. On November 17, 2009, the United States Food and Drug Administration (FDA) issued a public alert regarding updated labeling of clopidogrel that included the following statement: "New data show that when clopidogrel and omeprazole are taken together the effectiveness of clopidogrel is reduced." There is also evidence, however, that proton pump inhibitors may be associated with an increased risk of adverse cardiovascular events in the absence of clopidogrel.⁴⁷⁰ Concomitant use of proton pump inhibitors and thienopyridines was discussed in detail in an expert consensus document published by the American College of Cardiology Foundation, the College of Gastroenterology, and the American Heart Association.⁴⁷¹

Genetic polymorphisms that affect CYP2C19 activity are common and are associated with variability in the bioavailability of clopidogrel's active metabolite, affecting platelet inhibition and clinical outcomes, including the risk of stent thrombosis. On March 12, 2010, the FDA approved a new label for clopidogrel that contained a "boxed warning" regarding the drug's decreased efficacy in patients with impaired capacity to convert clopidogrel to an active metabolite, prompting publication of a document by the ACCF/AHA.⁴⁷²

The drug interactions and genetic polymorphisms that affect clopidogrel's metabolism can be approached using several strategies. One potential strategy is to employ genetic testing to identify patients who are heterozygous or homozygous for loss-of-function alleles that impair metabolism of clopidogrel, but genetic testing is expensive and has not gained widespread acceptance. Another approach is alternative dosing regimens of clopidogrel. Numerous studies have found that a 600-mg loading dose of clopidogrel, compared with a 300-mg loading dose, reduces the risk of major adverse cardiovascular events after PCI without increasing the risk of major bleeding.⁴⁷³ Also, increased loading and maintenance doses of clopidogrel produces greater platelet inhibition in patients who are heterozygous for the CYP2C19*2 loss of function allele.^{474,475} High residual platelet activity during clopidogrel therapy is associated with an increased risk of ischemic events in patients with ACS who undergo PCI, but a randomized trial that compared standard- and high-dose clopidogrel regimens in patients with high residual platelet activity failed to show a reduction in the incidence of cardiovascular deaths, nonfatal MI, or stent thrombosis 6 months after PCI with drug-eluting stents.^{476,477}

The CURRENT-OASIS 7 trial compared two regimens of clopidogrel in patients with ACS.^{464,465} The double-dose patients received a clopidogrel loading dose of 600 mg and a daily maintenance dose of 150 mg on days 2 to 7, then 75 mg daily, whereas the standard-dose group received a

loading dose of 300 mg followed by a daily maintenance dose of 75 mg. The frequency of major bleeding was greater among the patients who were randomized to the higher dose of clopidogrel. Although the double-dose regimen was associated with a reduction in cardiovascular events and stent thrombosis in ACS patients who underwent PCI, it is uncertain whether the higher maintenance dose that was administered for only 6 days provided any additional benefit beyond the documented benefit of the 600-mg loading dose.

A third approach is to prescribe other P2Y₁₂ inhibitors, such as prasugrel and ticagrelor. Cytochrome P450 genetic polymorphisms do not affect drug metabolite concentrations, inhibition of platelet aggregation, or clinical event rates in patients treated with prasugrel^{478,479} or ticagrelor.⁴⁸⁰ Also, compared with the combination of aspirin and clopidogrel, the combination of aspirin and ticagrelor reduced the risk of death in patients with ACS.¹¹³ Thus, the combinations of clopidogrel, prasugrel, or ticagrelor with aspirin were included in the Class I recommendations for dual antiplatelet therapy in the 2012 ACCF/AHA Focused Update of the Guideline for the Management of Patients with UA/Non-ST-Elevation Myocardial Infarction.²³

Whenever possible clopidogrel and ticagrelor should be discontinued at least 5 days before CABG surgery, and prasugrel should be stopped at least 7 days before CABG surgery, to attenuate the increased perioperative bleeding associated with inhibition of platelet P2Y₁₂ receptors.⁹⁷ Therefore, some practitioners prefer to withhold clopidogrel until the results of diagnostic cardiac catheterization are known, but this approach ignores the proven benefit of clopidogrel pretreatment in patients with ACS who undergo PCI⁴⁸¹ or CABG.⁴⁸² Also, CABG surgery can usually be deferred for 5 to 7 days, and percutaneous revascularization is more frequent than surgical revascularization in patients with ACS.⁴⁸² The CURE investigators concluded that the increased bleeding risk in patients who may require CABG surgery is outweighed by the overall reduction in ischemic events among all patients.⁴⁸² Also, among patients who were enrolled in the TRITON-TIMI 38 trial and underwent CABG, patients who were randomized to prasugrel had a lower rate of death after CABG, compared to the rate among patients who were randomized to clopidogrel, despite an increase in bleeding, platelet transfusion, and surgical reexploration for bleeding.⁴⁸³ Thus, a policy of withholding P2Y₁₂ antagonists until after coronary angiography may harm more patients than a policy of starting a P2Y₁₂ antagonist upon admission to the hospital.

Platelet Glycoprotein IIb/IIIa Receptor Antagonists

Discontinuation of either UFH or LMWH in patients with UA is associated with a rebound increase in thrombin generation,⁴⁸⁴ which may underlie the increase in death and MI that has been observed during the 12 hours after heparin is stopped in patients with ACS.^{485,486} Compared with patients who were randomized to a placebo group, patients who were randomized to treatment with a GP IIb/IIIa antagonist, eptifibatide, experienced significantly fewer deaths and MIs during the 12 hours after heparin was terminated.⁴⁸⁶

A retrospective analysis of the PURSUIT trial found that treatment with eptifibatide was associated with improved outcome among patients in whom cardiogenic shock

developed during hospitalization for ACS without persistent ST segment elevation.⁴⁸⁷ Although randomization to eptifibatide treatment did not affect the occurrence of shock, patients with shock who received eptifibatide had significantly reduced adjusted odds of death at 30 days (odds ratio 0.51; 95% CI 0.28 to 0.94; $p = 0.03$). It is unlikely that improved outcome after PCI was responsible for the beneficial effect of eptifibatide because only 25% of the patients with shock in PURSUIT underwent PCI.

Boersma and colleagues⁴⁸⁸ performed a meta-analysis of the individual patient data from six trials that randomized 31,402 patients with ACS without persistent ST segment elevation to a GP IIb/IIIa inhibitor treatment group (abciximab, eptifibatide, lamifiban, or tirofiban) or to a control group. Overall, there was a 9% reduction in the odds of death or MI at 30 days (10.8% versus 11.8%; odds ratio 0.91; 95% CI 0.84 to 0.98; $p = 0.015$).⁴⁸⁸ The baseline troponin value was available in a subset of 11,059 patients (35% of the entire cohort). Among the 45% of patients with a troponin T or I level 0.1 ng/mL or greater, there was a 15% reduction in the odds of death or MI at 30 days compared with that for the control group (10.3% versus 12%; odds ratio 0.85; 95% CI 0.71 to 1.03). No risk reduction was observed among patients with negative troponins (GP IIb/IIIa inhibitor 7% versus control 6.2%; odds ratio 1.17; 95% CI 0.94 to 1.44). Another meta-analysis of the same six trials found that the impact of GP IIb/IIIa antagonists on outcome varied with the revascularization strategy.⁴⁸⁹ The reduction of ischemic events was greater among patients who underwent PCI during the index hospitalization (odds ratio 0.82; $p = 0.01$) than among patients who were managed medically (odds ratio 0.95; $p = 0.27$).⁴⁸⁹ The corresponding number of events prevented per 1000 patients treated was 20 for patients who underwent PCI compared with 4 for patients treated medically.

The Early Glycoprotein IIb/IIIa Inhibition in Non-ST-Segment Elevation Acute Coronary Syndrome (EARLY ACS) trial compared two strategies of GP IIb/IIIa administration in 9492 patients with ACS without ST-segment elevation who were assigned to an invasive strategy.⁴⁹⁰ The patients were randomly assigned to either early eptifibatide beginning ≥ 12 hours before coronary angiography, or a matching placebo infusion with provisional, delayed use of eptifibatide after angiography. At 30 days the rate of death or MI was 11.2% in the early-eptifibatide group compared with 12.3% in the delayed eptifibatide group (odds ratio 0.89; 95% CI 0.79 to 1.01; $p = 0.08$). The rates of bleeding and red cell transfusion, but not severe bleeding, were significantly higher in the early-eptifibatide group.

Several Class I, II, and III recommendations for the use of platelet GP IIb/IIIa antagonists are included in the 2012 ACCF/AHA Focused Update of the ACC/AHA Guideline for the Management of Patients with UA/Non-ST-Elevation Myocardial Infarction.²³ Patients with definite UA/NSTEMI at medium or high risk and in whom an initial invasive strategy is selected should receive dual antiplatelet therapy on presentation: either a GP IIb/IIIa inhibitor (eptifibatide and tirofiban are preferred) or a P2Y₁₂ receptor inhibitor (clopidogrel or ticagrelor before PCI, and clopidogrel, prasugrel, or ticagrelor at the time of PCI) should be added to aspirin (Class I). For patients in whom an initial conservative strategy is selected, the guidelines recommend that

patients with subsequent heart failure, serious arrhythmias, or recurrent symptoms or ischemia should undergo diagnostic angiography preceded by “upstream” administration of either a GP IIb/IIIa inhibitor (eptifibatide or tirofiban), clopidogrel, or ticagrelor in combination with aspirin and anticoagulant therapy (Class I). For patients in whom an initial conservative strategy is selected, the guidelines state that it is reasonable to add a GP IIb/IIIa inhibitor to aspirin and a P2Y₁₂ receptor inhibitor (clopidogrel or ticagrelor) before diagnostic angiography when there is recurrent ischemic discomfort (Class IIa). Among patients who are selected for an initial invasive strategy, upstream administration of a GP IIb/IIIa inhibitor before diagnostic angiography may be omitted in patients who are treated with both bivalirudin and at least 300 mg of clopidogrel at least 6 hours earlier than angiography or PCI (Class IIa). Upstream administration of a GP IIb/IIIa inhibitor is not recommended in UA/NSTEMI patients who are already receiving aspirin and a P2Y₁₂ receptor inhibitor and who are either at low risk for ischemic events or at high risk of bleeding (Class III). Finally, abciximab should not be administered to patients in whom PCI is not planned (Class III), presumably because the GUSTO IV ACS trial failed to show a benefit of abciximab among patients with ACS who did not undergo early coronary revascularization.⁴⁹¹

GP IIb/IIIa antagonists increase the risk of bleeding, frequently involving the access site used for cardiac catheterization, but the risk of intracranial hemorrhage is not increased.⁴⁸⁸ The meta-analysis discussed earlier found that the risk of major bleeding was 2.4% among patients who were randomized to a GP IIb/IIIa antagonist compared with 1.4% among control patients (odds ratio 1.62; 95% CI 1.36 to 1.94; $p < 0.0001$).⁴⁸⁸ One preventable cause of bleeding is excess dosing of a GP IIb/IIIa antagonist, which occurred in 26.8% of patients with non-ST segment elevation ACS who were enrolled in the CRUSADE registry by 387 hospitals in 2004.⁴⁹²

A complete blood count including platelet count should be included in monitoring during administration of GP IIb/IIIa antagonists. A review of eight large placebo-controlled randomized trials, however, concluded that abciximab, but not eptifibatide or tirofiban, increases the incidence of thrombocytopenia.⁴⁹³

ANTITHROMBIN THERAPY

Unfractionated Heparin

At least seven randomized, placebo-controlled trials have compared UFH plus aspirin with aspirin alone in patients with UA, but none of them was adequately powered to detect a reduction in the rate of death or MI during hospitalization. A meta-analysis of six of the trials concluded that the addition of UFH to aspirin reduced the risk of death or MI during treatment by 33% (RR 0.67; 95% CI 0.44 to 1.02; $p = 0.06$).⁴⁹⁴ Therefore, the ACC/AHA Practice Guidelines include intravenous UFH in the list of Class I recommendations for patients with UA or NSTEMI.¹ The guidelines also recommend daily measurement of hemoglobin or hematocrit and platelet count during treatment with UFH because of the increased risks of bleeding and thrombocytopenia. An analysis of patients who were enrolled in the CRUSADE registry in 2004 found that bleeding was related to excess

dosing of UFH, which occurred in 32.8% of patients who received UFH.⁴⁹²

As discussed earlier, a rebound increase in thrombin generation with reactivation of UA has been observed after the discontinuation of UFH. One clinical trial observed an eightfold increase in death and a twofold increase in MI during the 12 hours after heparin was discontinued.⁴⁸⁶ The rate of events during the 12 hours after heparin was terminated was significantly lower among patients who were randomized to treatment with eptifibatide than among patients in the placebo group.⁴⁸⁶

Low-Molecular-Weight Heparin

The FRISC study randomized 1506 patients with UA or non-Q wave MI to receive placebo or dalteparin, an LMWH, twice daily for 6 days, followed by once daily for 35 to 45 days.⁴⁹⁵ A 63% reduction in the risk of death or MI occurred during the first 6 days (4.8% versus 1.8%; $p = 0.001$). Subsequently, 21,946 patients with non-ST segment elevation ACS have been enrolled in six randomized trials that compared enoxaparin, another LMWH, with UFH. A meta-analysis of the trials found no significant difference in death at 30 days for enoxaparin versus UFH (3% versus 3%; odds ratio 1.00; 95% CI 0.85 to 1.17).⁴⁹⁶ A statistically significant reduction was observed in the combined end points of death and nonfatal MI at 30 days for enoxaparin versus UFH (10.1% versus 11%; odds ratio 0.91; 95% CI 0.83 to 0.99).

Although it had been hypothesized that the risk of bleeding would be less during treatment with LMWH than with UFH, the meta-analysis performed by Petersen and colleagues⁴⁹⁶ found no significant difference between enoxaparin and UFH in the rates of blood transfusion or major bleeding at 7 days after initiation of the study treatment. The risk of bleeding during treatment with LMWH may be increased by excess dosing, which occurred in 13.8% of patients who were enrolled in the CRUSADE registry in 2004 and received LMWH.⁴⁹²

The current ACCF/AHA guidelines recommend the addition of anticoagulant therapy to antiplatelet therapy in patients with UA or NSTEMI as soon as possible after presentation.²³ Both UFH and enoxaparin received Class I recommendations for patients selected for either an invasive or conservative strategy.²³ Enoxaparin or fondaparinux is preferable to UFH in patients selected for an initial conservative strategy unless CABG is planned within 2 hours (Class IIa).²³

DIRECT THROMBIN INHIBITORS

Direct thrombin inhibitors, such as hirudin and bivalirudin, have been evaluated in patients with ACS. The ACUTY trial was an open-label, randomized, multicenter trial that compared heparin plus a GP IIb/IIIa antagonist, bivalirudin plus a GP IIb/IIIa antagonist, and bivalirudin alone in patients with moderate-risk or high-risk non-ST segment elevation ACS who were undergoing an early invasive strategy.⁴⁹⁷⁻⁴⁹⁹ NSTEMI was present in 59% of patients, and 41% had UA. Compared with patients who received a GP IIb/IIIa antagonist plus UFH or enoxaparin, patients who received bivalirudin alone experienced significantly less non-CABG-related major bleeding (3% versus 5.7%; RR 0.53; 95% CI 0.43 to 0.65). Compared with heparin plus a GP IIb/IIIa antagonist, bivalirudin alone resulted in a noninferior rate of the

composite ischemia end point (7.3% versus 7.8%, respectively; RR 1.08; 95% CI 0.93 to 1.24; $p = 0.32$). Administration of bivalirudin plus a GP IIb/IIIa antagonist, as compared with heparin plus a GP IIb/IIIa antagonist, resulted in non-inferior 30-day rates of the composite ischemia end point (7.7% versus 7.3%, respectively; RR 1.07; 95% CI 0.92 to 1.23; $p = 0.39$) and major bleeding (5.3% versus 5.7%, respectively; RR 0.93; 95% CI 0.78 to 1.10; $p = 0.38$). Bivalirudin is a Class I anticoagulant in patients with UA or NSTEMI who are selected for an invasive strategy.¹

FACTOR XA INHIBITORS

Several factor Xa inhibitors, fondaparinux,⁵⁰⁰ apixaban,⁵⁰¹ and rivaroxaban, have been studied in patients with ACS. The OASIS-5 trial compared fondaparinux with enoxaparin for a mean of 6 days in 20,078 patients with ACS.⁵⁰⁰ The rate of major bleeding at 9 days was lower with fondaparinux than with enoxaparin (2.2% versus 4.1%; hazard ratio 0.52; $p < 0.001$). Also, the number of deaths at 30 days was significantly reduced by fondaparinux compared with enoxaparin (295 versus 352, $p = 0.02$). Fondaparinux is preferable to UFH or enoxaparin for patients with UA or NSTEMI who are selected to a conservative strategy and have an increased risk of bleeding (Class I).²³ Fondaparinux or enoxaparin are preferable to UFH in patients with UA or NSTEMI who are selected for an initial conservative strategy unless CABG is planned within 24 hours (Class IIa).²³ Because of the risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant during PCI, and an additional anticoagulant with antifactor IIa activity should be administered.²¹

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Little information is available regarding the administration of ACE inhibitors to patients with NSTEMI because most of the ACE inhibitor trials did not report subgroup analyses of patients with STEMI or NSTEMI. The Survival of Myocardial Infarction Long-Term Evaluation (SMILE) study enrolled 1556 patients with acute anterior MI who were not eligible for fibrinolytic therapy.⁵⁰² The patients were randomized to receive 6-week courses of placebo or zofenopril, an ACE inhibitor. Among the 526 patients with ECG criteria for NSTEMI, death or severe CHF occurred in 10.3% (28/273) of placebo patients and 3.6% (9/253) of zofenopril patients (RR reduction 65%; 95% CI 20% to 80%; $p = 0.003$).⁵⁰³ The 1-year mortality rate also was significantly reduced by zofenopril (7.9% versus 15.8%; RR reduction 43%; 95% CI 14% to 57%; $p = 0.036$).

LIPID-LOWERING THERAPY

As discussed earlier, the 4S,³⁴⁸ CARE,³⁴⁹ and LIPID³⁵⁰ trials have established the long-term benefits of starting statin therapy 3 months or later after hospitalization for an MI or UA. Analysis of the LIPID trial showed that initiation of pravastatin 40 mg daily 3 to 36 months after hospitalization for UA significantly reduced the risk of several end points, including death (RR 0.74; 95% CI 0.50 to 0.91; $p = 0.004$) and nonfatal MI (RR 0.67; 95% CI 0.51 to 0.88; $p = 0.004$).⁵⁰⁴

Data are conflicting regarding the benefit of early initiation of lipid-lowering therapy in patients with ACS. A retrospective analysis of the outcomes in 1616 patients with ACS concluded that statin pretreatment is associated with

improved clinical outcome, whereas the discontinuation of statins after symptom onset is associated with an increased risk of death and nonfatal MI within 30 days.⁵⁰⁵ An observational study that combined data from the GUSTO IIB and PURSUIT trials concluded that prescription of a lipid-lowering drug at hospital discharge was independently associated with a reduced risk of death at 6 months (hazard ratio 0.67; 95% CI 0.48 to 0.95; $p = 0.023$).⁵⁰⁶ Another study of 12,365 patients with ACS concluded that there was no impact of early initiation of statin therapy on death, MI, or severe recurrent ischemia at 90 days.⁵⁰⁷

Numerous randomized trials have investigated the effects of statins on outcomes in patients with ACS. Compared with placebo, treatment with atorvastatin 80 mg daily beginning 24 to 96 hours after hospital admission reduced the rate of recurrent ischemic events at 16 weeks.⁵⁰⁸ The Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22 (PROVE IT-TIMI 22) study compared atorvastatin 80 mg daily with pravastatin 40 mg daily started within 10 days of hospitalization for an ACS.³⁵² The primary end point was a composite of death, MI, UA, revascularization, and stroke. The rates for the primary end point at 2 years were 22.4% in the atorvastatin group and 26.3% in the pravastatin group, representing a 16% reduction in the hazard ratio in favor of atorvastatin (95% CI 5% to 26%; $p = 0.005$).

At least two meta-analyses of relevant randomized controlled trials have been performed to estimate the effects of early treatment with statins on short-term outcomes in patients with ACS.^{381,382} One analysis of 12 randomized trials concluded that statin therapy initiated within 14 days of hospital admission does not reduce the risk of death, MI, or stroke during the first 4 months after ACS.³⁸¹ Another meta-analysis of 13 randomized trials concluded that early statin therapy reduces the rates of death and cardiovascular events after 4 months of treatment.³⁸²

INVASIVE VERSUS CONSERVATIVE MANAGEMENT

At least eight randomized trials have compared early invasive and early conservative management strategies for patients with ACS. Patients who are managed by an early conservative strategy undergo coronary angiography if evidence points to spontaneous recurrent ischemia or if results of stress testing are strongly positive despite medical therapy. Patients who are managed using an early invasive strategy undergo routine coronary angiography and coronary revascularization as indicated. Three relatively large trials demonstrated better short-term and long-term outcomes among patients randomized to the early invasive strategy compared with the early conservative strategy: FRISC II,⁵⁰⁹⁻⁵¹¹ TACTICS-TIMI 18,⁴³⁷ and the Randomized Intervention Trial of Unstable Angina-3 (RITA-3).^{512,513} The FRISC II⁵⁰⁹⁻⁵¹¹ and TACTICS-TIMI 18 trials randomized 2457 and 2220 patients, respectively, with UA or NSTEMI to either an early conservative or an early invasive strategy. Both trials found that the early invasive strategy was associated with a lower risk of death or MI at 6 months compared with the early conservative strategy: 9.4% versus 12.1% (RR 0.78; 95% CI 0.62 to 0.98; $p = 0.031$) for FRISC II and 7.3% versus 9.5% (odds ratio 0.74; 95% CI 0.54 to 1.00; $p < 0.05$) for TIMI 18. The early invasive strategy also was associated with a reduced rate of rehospitalization for ACS in both trials. After follow-up

for 2 years in the FRISC II trial, patients who were randomized to the early invasive arm experienced lower rates of MI (9.2% versus 12.7%; RR 0.72; 95% CI 0.57 to 0.91; $p = 0.005$) and overall mortality (3.7% versus 5.4%; RR 0.68; 95% CI 0.47 to 0.98; $p = 0.038$).⁵¹¹ The RITA-3 study randomized 1810 patients with non-ST elevation acute coronary syndromes to early invasive or early conservative treatment.^{512,513} After a median follow-up period of 5 years, 142 (16.6%) patients randomized to the early intervention group and 178 (20%) patients assigned to the early conservative group died or had a nonfatal MI (odds ratio 0.78; 95% CI 0.61 to 0.99; $p = 0.044$). The death rates were 12% for the intervention group versus 15% for the conservative group (odds ratio 0.76; 95% CI 0.58 to 1.00; $p = 0.054$).

A meta-analysis of the 5-year outcomes of three large trials found that cardiovascular death or MI occurred in 14.7% (389 of 2721) of patients randomized to a routine invasive strategy versus 17.9% (475 of 2746) of patients who were randomized to a selective invasive strategy (hazard ratio 0.81, 95% CI 0.71 to 0.93; $p = 0.002$).⁵¹⁴ The absolute risk reductions for the combined end point of cardiovascular death or MI were 2%, 3.8%, and 11.1% for the low-, moderate-, and high-risk patients.

The early invasive strategy confers the greatest benefit in patients who are characterized by high-risk indicators such as ST segment depression^{436,437} or elevated troponin.⁴⁴⁷ Therefore, elevated troponin T or I and new or presumably new ST segment depression are included in a list of 13 high-risk indicators that warrant an early invasive strategy in patients with UA or NSTEMI (Box 30.7).²³ A meta-analysis of nine randomized trials that compared an invasive versus a conservative strategy in patients with non-ST segment elevation acute coronary syndromes included 1789 patients with diabetes mellitus.⁵¹⁵ Compared with the conservative strategy, the invasive strategy was associated with a 3.7% absolute risk reduction of nonfatal MI and a 5.1% absolute risk reduction of death, MI, or rehospitalization with ACS among patients with diabetes.⁵¹⁵ Consequently, diabetes is included in the list of 13 high-risk indicators that warrant an early invasive strategy in patients with non-ST segment elevation ACS.²³ An early conservative strategy may be selected for patients with a low TIMI or GRACE score and who lack the high-risk indicators listed in Box 30.7.

Several studies have attempted to determine the optimal timing of revascularization with PCI among patients with UA or NSTEMI who are selected for early invasive management. The Timing of Intervention in Acute Coronary Syndrome (TIMACS) trial randomly assigned 3031 patients with ACS without ST segment elevation to two groups: routine early intervention (coronary angiography ≤ 24 hours after randomization) or delayed intervention (coronary angiography ≥ 36 hours after randomization).⁵¹⁶ The median time to coronary angiography was 14 hours for the early-intervention group and 50 hours for the delayed-intervention group. Early intervention improved the primary composite end point of death, MI, or stroke at 6 months in the one third of patients who were at highest risk (hazard ratio 0.65; 95% CI 0.48 to 0.89), but not in the two thirds of patients at low or intermediate risk (hazard ratio 1.12; 95% CI 0.81 to 1.56). PCI was performed in 7749 patients with ACS without ST segment elevation who were enrolled in the ACUTY randomized trial.⁵¹⁷ Delay to PCI more than

Box 30.7 Initial Treatment Strategy: Invasive Versus Conservative Strategy

Invasive Strategy Preferred

1. Recurrent angina/ischemia at rest or with low-level activities despite intensive medical therapy
2. Elevated troponin T or troponin I
3. New or presumably new ST segment depression
4. Signs or symptoms of heart failure or new or worsening mitral regurgitation
5. High-risk findings from noninvasive testing
6. Reduced left ventricular function (LVEF less than 40%)
7. Hemodynamic instability
8. Sustained ventricular tachycardia
9. PCI within 6 months
10. Prior CABG surgery
11. High risk score (e.g., TIMI, GRACE)
12. Mild to moderate renal dysfunction
13. Diabetes mellitus

Conservative Strategy Preferred

1. Low risk score (e.g., TIMI, GRACE)
2. Patient or physician preference in the absence of high-risk features

CABG, coronary artery bypass graft; GRACE, Global Registry of Acute Coronary Events; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; TIMI, thrombolysis in myocardial infarction.

From Jneid H, Anderson JL, Wright RS, et al: 2012 ACCF/AHA focused update of the guideline for the management of patients with UA/non-ST-elevation myocardial infarction (updating the 2007 guideline and replacing the 2011 focused update): A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2012;60:645-681.

24 hours after presentation was associated with a significant increase in the mortality and MI rates at 30 days. A delay to PCI more than 24 hours after presentation was an independent predictor of both 30-day and 1-year mortality.

The ACCF/AHA Guidelines provide recommendations regarding the mode of coronary revascularization in patients with UA or NSTEMI²³ (Table 30.4). Coronary anatomy and left ventricular EF are two of the key factors that determine whether percutaneous or surgical revascularization is preferable in a patient with UA or NSTEMI. Although the guidelines do not specify a preference for PCI or CABG surgery in patients with a non-Q wave MI, periprocedural mortality was greater after CABG surgery than after PCI in the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) trial.⁵¹⁸ Thirty-day mortality was 11.6% after CABG surgery (11/95 patients), compared with 0% after PCI (0/98 patients).⁵¹⁸

LONG-TERM MEDICAL THERAPY

Prescription of evidence-based medical therapy at the time of hospital discharge has a major impact on outcome in patients with ACS. Mukherjee and coworkers⁵¹⁹ calculated an appropriateness score based on the use of antiplatelet agents, β -blockers, ACE inhibitors, and lipid-lowering agents

Table 30.4 ACCF/AHA Practice Guidelines: Recommendations for Revascularization with PCI and CABG in Patients with Unstable Angina/Non-ST Segment Elevation Myocardial Infarction

Extent of Disease	Treatment	Class
Left main disease,* candidate for CABG	CABG	I
	PCI	III
Left main disease, not candidate for CABG	PCI	IIa
Three-vessel disease with LVEF < 0.5	CABG	I
Multivessel disease including proximal LAD with LVEF < 0.5 or treated diabetes	CABG PCI	I IIb
Multivessel disease with LVEF > 0.5 and without diabetes	PCI or CABG CABG	I I
Two-vessel disease with significant proximal LAD stenosis and either LVEF < 0.5 or ischemia on noninvasive testing	PCI	IIb
One- or two-vessel disease with or without significant proximal LAD stenosis but with a large area of viable myocardium and high-risk criteria on noninvasive testing	CABG or PCI	I
One-vessel disease with proximal LAD	CABG or PCI	IIa [†]
One- or two-vessel disease without significant proximal LAD stenosis with no current symptoms or symptoms that are unlikely to be ischemic and who have no ischemia on noninvasive testing	CABG or PCI	III [†]
Insignificant coronary stenosis	CABG or PCI	III

* $\geq 50\%$ diameter stenosis.

[†]Class/level of evidence IA if severe angina persists despite medical therapy.

ACCF, American College of Cardiology Foundation; AHA, American Heart Association; CABG, coronary artery bypass grafting; LVEF, ejection fraction; LAD, left anterior descending (artery); PCI, percutaneous intervention.

From Anderson JL, Adams CD, Antman EM, et al: 2011 ACCF/AHA focused update incorporated into the ACC/AHA 2007 guidelines for the management of patients with UA/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2011;57:e215-e367.

in patients with an indication for each class of drugs. The use of combination evidence-based medical therapies was independently associated with lower 6-month mortality among a cohort of 1358 patients with ACS (55% NSTEMI, 30% UA, and 15% STEMI). The odds ratio for death for prescription of all indicated medications versus none of the indicated medications was 0.10 (95% CI 0.03 to 0.42; $p < 0.0001$).

The ACCF/AHA guidelines for the management of patients with UA and NSTEMI include multiple Class I recommendations for long-term medical therapy (Box 30.8).¹ Aspirin 75 to 162 mg daily should be continued indefinitely.²³ Clopidogrel should be prescribed for at least 1 month, and ideally up to 1 year in patients treated medically

without stenting. Patients who receive bare-metal stents should be treated with a P2Y₁₂ inhibitor for at least 1 month and ideally up to 1 year, whereas patients who receive drug-eluting stents should be treated with a P2Y₁₂ inhibitor for a minimum of 12 months.⁹⁸ β -Blockers are recommended for all patients without contraindications. ACE inhibitors are recommended for patients with CHF, left ventricular EF less than 40%, hypertension, or diabetes. Lipid-lowering agents are recommended for patients with an LDL cholesterol level greater than 100 mg/dL after dietary manipulation.

Box 30.8 Class I Recommendations for Long-Term Medical Therapy for Patients with Unstable Angina/Non-ST Segment Elevation Myocardial Infarction

1. For UA/NSTEMI patients treated medically without stenting, aspirin (75 to 162 mg/day) should be prescribed indefinitely; clopidogrel should be prescribed for at least 1 month and ideally up to 1 year.
2. β -Blockers are indicated for all patients recovering from UA/NSTEMI unless contraindicated. Treatment should begin within a few days of the event, if not initiated acutely, and should be continued indefinitely. Patients recovering from UA/NSTEMI with moderate or severe LV failure should receive β -blocker therapy with a gradual titration scheme.
3. Angiotensin-converting enzyme inhibitors should be given and continued indefinitely for patients recovering from UA/NSTEMI with heart failure, LV dysfunction (LVEF less than 0.4), hypertension, or diabetes mellitus, unless contraindicated.
4. An angiotensin receptor blocker should be prescribed at discharge to those UA/NSTEMI patients who are intolerant of an ACE inhibitor and who have either clinical or radiologic signs of heart failure and LVEF less than 0.4.
5. Long-term aldosterone receptor blockade should be prescribed for UA/NSTEMI patients without significant renal dysfunction (estimated creatinine clearance should be greater than 30 mL/min) or hyperkalemia (potassium should be less than or equal to 5 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor, have an LVEF less than or equal to 0.4, and have either symptomatic heart failure or diabetes mellitus.
6. The following lipid recommendations are beneficial:
 - a. Lipid management should include assessment of a fasting lipid profile for all patients, within 24 hours of hospitalization.
 - b. Statins, in the absence of contraindications, regardless of baseline LDL-C and diet modification, should be given to post-UA/NSTEMI patients, including postrevascularization patients.
 - c. For hospitalized patients, lipid-lowering medications should be initiated before discharge.
 - d. For UA/NSTEMI patients with elevated LDL-C (greater than or equal to 100 mg/dL), cholesterol-lowering therapy should be initiated or intensified to achieve an LDL-C of less than 100 mg/dL. Further titration to less than 70 mg/dL is reasonable.

ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; EF, ejection fraction; LDL, low-density lipoprotein.

Modified slightly from Anderson JL, Adams CD, Antman EM, et al: 2011 ACCF/AHA focused update incorporated into the ACC/AHA 2007 guidelines for the management of patients with UA/non-ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2011;57:e215-e367.

KEY POINTS

- The ACSs—UA, NSTEMI, and STEMI—all share a common pathophysiology: erosion or rupture of an atherosclerotic plaque that precipitates either nonocclusive or occlusive coronary artery thrombosis.
- Patients with suspected STEMI should have an ECG performed and interpreted within 10 minutes of presentation, and serial ECGs should be performed at intervals of 5 to 10 minutes in patients with a nondiagnostic initial ECG and clinical findings strongly suggestive of STEMI. Right-sided lead tracings should be obtained to screen for right ventricular MI in patients with inferior STEMI.
- The two Class I indications for fibrinolytic therapy in patients with STEMI are (1) symptom onset within the prior 12 hours and ST elevation greater than 0.1 mV in at least two contiguous precordial leads or at least two adjacent limb leads and (2) symptom onset within the prior 12 hours and new or presumably new left bundle branch block.
- Fibrinolytic therapy should be initiated within 30 minutes of presentation.
- Intracranial hemorrhage should be ruled out in any patient with a change in neurologic status during or after fibrinolytic therapy.
- Nitrates are indicated for relief of ischemic discomfort in patients with STEMI, but large clinical trials did not demonstrate a reduction in mortality among patients who received nitroglycerin over prolonged periods after acute MI.
- Aspirin has been shown to reduce mortality in patients with acute MI or UA. Patients with STEMI should receive 162 to 325 mg of non-enteric-coated aspirin, and the aspirin tablets should be chewed.
- The addition of clopidogrel to aspirin has been shown to improve angiographic and clinical outcomes in patients with STEMI or ACS without ST segment elevation.
- A meta-analysis of 23 randomized trials concluded that the rates of short-term death, nonfatal reinfarction, stroke, and the combined end point of all three were lower for primary coronary intervention than for fibrinolytic therapy in patients with STEMI.
- Balloon inflation should occur within 90 minutes of presentation in patients with STEMI who undergo primary coronary intervention.

Continued on following page

KEY POINTS (Continued)

- Primary coronary intervention is preferable to fibrinolytic therapy in patients with STEMI under the following circumstances: the diagnosis of STEMI is uncertain, fibrinolysis is contraindicated, the door-to-balloon time is less than 90 minutes and the difference between the door-to-balloon and door-to-needle times is less than 60 minutes, and the patient is in Killip class III or IV (pulmonary edema or cardiogenic shock).
- In patients with acute MI, the early administration of β -blockers reduces the rate of reinfarction and chronic administration improves long-term survival.
- An ACE inhibitor should be administered orally within the first 24 hours of STEMI to patients with anterior infarction, pulmonary congestion, or left ventricular EF less than 40% in the absence of hypotension.
- An angiotensin receptor blocker should be administered to patients with STEMI who are intolerant of ACE inhibitors and have either CHF or a left ventricular EF less than 40%.
- Long-term aldosterone blockade should be prescribed for post-STEMI patients without significant renal dysfunction or hyperkalemia who are already receiving therapeutic doses of an ACE inhibitor, have a left ventricular EF of 40% or less, and have either diabetes or symptomatic CHF.
- Diltiazem and verapamil are contraindicated in patients with STEMI and associated systolic left ventricular dysfunction and CHF.
- Lipid-lowering therapy is indicated at the time of hospital discharge in all patients with STEMI.
- Patients with UA or NSTEMI should be treated with both an anticoagulant (UFH, enoxaparin, or fondaparinux) and at least dual antiplatelet therapy with aspirin and an antagonist of the platelet P2Y₁₂ receptor (clopidogrel, prasugrel, or ticagrelor).
- An early invasive strategy is favored in patients with UA or NSTEMI who have any of the following high-risk indicators: recurrent angina or ischemia despite intensive anti-ischemic therapy, elevated troponin, new or presumably new ST segment depression, recurrent angina or ischemia with CHF or new or worsening mitral regurgitation, a high-risk noninvasive stress test, left ventricular EF less than 40%, hemodynamic instability, sustained ventricular tachycardia, PCI within the past 6 months, prior CABG surgery, or a high risk score (TIMI, GRACE).

CONCLUSIONS

Management of serious cardiac arrhythmias is the shared responsibility of emergency specialists: critical care physicians, cardiologists, and electrophysiologists. The past 10 years have produced only modest changes in acute and subacute therapy of tachyarrhythmias. Antiarrhythmic drugs remain the mainstay of acute therapy for supraventricular arrhythmias and hemodynamically stable ventricular tachycardia. Temporary pacing remains the “gold standard” urgent/emergent therapy for symptomatic bradyarrhythmias. Permanent pacing is still the only option for treatment of chronic bradycardias. By contrast, dramatic improvement and change have occurred in the chronic therapy of tachyarrhythmias. Most supraventricular tachycardias can now be cured by catheter ablation. Patients with structural heart disease at risk for sudden cardiac death (SCD) and those resuscitated from hemodynamically unstable ventricular

tachyarrhythmias now are managed with implantable defibrillators, with antiarrhythmic drugs used primarily as an adjunct for patients receiving frequent shocks.

Critical care physicians deal with a plethora of medical and surgical problems in their patients. Arrhythmias may be the primary abnormality or may be secondary to myocardial ischemia, electrolyte imbalance, or toxic/metabolic disturbances. Optimal management of arrhythmias requires expertise in electrocardiography and clinical pharmacology as well as knowledge of arrhythmia precipitants, including proarrhythmia caused by antiarrhythmic drugs.¹ The responsibility of the critical care physician is to facilitate transition from acute to chronic care by referring the patient with an arrhythmia to a cardiologist or an electrophysiologist. Therefore, the major emphasis of this chapter is on acute care of the patients with arrhythmias.

BRADYCARDIAS

Bradyarrhythmias usually present as either sinus node dysfunction (SND) or atrioventricular blockade (AV block). Bradyarrhythmias and indications and techniques for temporary cardiac pacing are reviewed extensively in Chapter 5. A brief overview is included here to highlight important issues for the intensivist.

SINUS BRADYCARDIA AND SINUS NODE DYSFUNCTION

Sinus bradycardia is generally defined as periods of sinus rhythm with rates less than 60 beats per minute. In the absence of symptoms, it usually is benign and requires no treatment. Sinus bradycardia is common in young adults (particularly the physically fit). Nocturnal rates of 35 to 40 beats per minute and pauses during sleep of 2 seconds or longer are not uncommon. Sinus arrhythmia (Fig. 31.1) is a normal variant in which there are respirophasic changes in the RR interval on electrocardiogram (ECG) (prolongation of RR intervals during expiration).

Sinus bradycardia may also be a manifestation of certain pathologic conditions such as increased intracranial pressure, oculocardiac reflex after ophthalmologic surgery, cervical and mediastinal tumors, hypothyroidism, hypothermia, gram-negative sepsis, Chagas' disease, depression, and anorexia nervosa. Sinus bradycardia is often seen after cardiac transplantation. Beta blockers, parasympathomimetic agents, calcium antagonists, amiodarone, and lithium commonly produce sinus bradycardia. Digoxin, in therapeutic doses, usually does not markedly affect the sinus node and is relatively safe to use in patients with SND.² Sinus bradycardia complicates 10% to 15% of acute myocardial infarctions and is most common with inferior infarcts. It also may be seen after successful thrombolysis. In the absence of hemodynamic compromise, it is associated with a more favorable prognosis than sinus tachycardia.³

Short-term pharmacologic enhancement of the sinus rate may be accomplished using atropine, catecholamines, or theophylline. Isoproterenol should be avoided in patients with ischemic heart disease and hypertrophic cardiomyopathy. No safe, reliable drug is available for long-term management of sinus bradycardia. Temporary pacing may suffice when the underlying condition is reversible. Permanent pacing should be employed to alleviate persistent bradycardia and symptoms.

Sinus bradycardia (with or without AV block) may occur during periods of autonomic instability. Examples include carotid hypersensitivity and neurocardiogenic syncope. These syndromes have cardioinhibitory (bradycardic), vasodepressor (vasodilatory), and mixed forms. Permanent pacing (which must include the ability to pace the right ventricle for heart block) is a well-established therapy for

cardioinhibitory carotid sinus hypersensitivity. Neurocardiogenic syncope generally is a benign condition that usually can be managed without permanent pacemaker therapy. However, treatment for patients with frequent and severe cardioinhibitory spells, especially those in whom asystolic periods exceeding 5 seconds can be demonstrated clinically or during head-up tilt table testing, may include palliative pacemaker therapy.⁴

SND may manifest in a variety of ways, including persistent sinus bradycardia, sinus pause or arrest, sinoatrial (SA) exit block, and the bradycardia-tachycardia syndrome.

SA exit block occurs when an impulse from the sinus node is not conducted to the surrounding atrium. First-degree SA exit block results from intranodal conduction delay and is not manifest on surface ECG. Complete (third-degree) SA exit block will manifest as sinus arrest. Only second-degree SA exit block is uniquely manifest on surface ECG.

Type I second-degree SA exit block is characterized by progressive PP interval shortening before pauses that are less than two PP cycles in duration. In type II second-degree SA exit block, pauses are exact multiples of the basic PP interval. SA exit block usually is transient and often is reversible. Its presence should prompt a search for underlying causes such as enhanced vagal tone, acute myocarditis or infarction, or drug effect (as from digitalis).

Symptomatic SND virtually always requires permanent pacing. Patients with concomitant supraventricular tachycardias may require supplemental antiarrhythmic therapy. Drug therapy may aggravate the bradycardia and in many instances should be initiated after device placement. Catheter ablation may palliate or eliminate the tachyarrhythmia.

ATRIOVENTRICULAR BLOCK

The various forms of heart block are disturbances of impulse conduction. Heart block may be transient or permanent. The following paragraphs focus on disturbances of AV conduction.

In reality, first-degree AV block involves no AV block at all but is due to delayed conduction from the atria to the ventricles. Every atrial impulse is conducted to the ventricles in a delayed fashion such that the PR interval is greater than 200 ms. If the QRS complex on the surface echocardiogram is narrow, the delay nearly always is in the AV node. In the presence of a wide QRS complex, the delay may be in either the AV node or the His-Purkinje system.

Second-degree AV block is classified as Mobitz type I (Wenckebach), Mobitz type II, 2:1 AV block, or high-degree AV block. In Mobitz I (Wenckebach) block, PP intervals are constant, with gradual PR prolongation before failure of impulse conduction (nonconducted P wave) (Fig. 31.2). Although classic Wenckebach block involves simultaneous shortening of successive RR intervals before AV block,

Figure 31.1 Sinus arrhythmia. A normal variant of sinus rhythm is sinus arrhythmia. Here, there are respirophasic changes in the RR interval on electrocardiogram (gradual prolongation of RR intervals during expiration).

Figure 31.2 Second-degree atrioventricular block, Mobitz type I (Wenckebach). The PR interval progressively lengthens until a P wave is not conducted. The intervals may be fixed or variable. In this example, there are four P waves for every three QRS complexes.

Figure 31.3 Second-degree atrioventricular block, Mobitz type II. There is a constant PR interval until a P wave is suddenly not conducted. Note the QRS is prolonged to approximately 120 ms.

Figure 31.4 A 2:1 atrioventricular (AV) block. In the setting of AV block with a 2:1 interval, it is not possible to determine by surface electrocardiogram if the block is Mobitz type I or Mobitz type II. Narrow QRS complexes generally result from AV nodal block. Wide QRS complexes are compatible with block in either the AV node or His-Purkinje system.

Figure 31.5 High-grade atrioventricular (AV) block. Two or more P waves are not followed by a QRS complex. In this example, there are three P waves for each QRS complex, an example of 3:1 high-grade AV block.

atypical alternations in RR intervals actually are more common. In younger people, Mobitz I AV block with normal QRS complexes generally is benign and does not progress to more advanced AV conduction disturbances. In older patients, the prognosis may be similar to that with Mobitz II block. Mobitz I second-degree AV block may accompany inferior myocardial infarction. The condition is benign, with a favorable prognosis, in the absence of hemodynamic compromise. The conduction disturbance usually is transient, and permanent pacing is not required.

Mobitz II AV block is characterized by sudden failure of atrial impulse conduction without prior PR prolongation (Fig. 31.3). This form of AV block frequently heralds development of complete AV block and Adams-Stokes syncope. Mobitz II second-degree AV block in the setting of anterior infarction is associated with pump failure and high mortality rates. Survivors should receive permanent pacemakers.

In general, the surface ECG allows the clinician to localize the site of AV block without the use of invasive electrophysiologic testing. Mobitz type I AV block with a narrow QRS almost always occurs at the AV node. Rarely, Mobitz I second-degree AV block may have an intra-His location. Mobitz I AV block with wide QRS complexes may occur in either the AV node or the His-Purkinje system. Mobitz II second-degree AV block (particularly in the presence of wide QRS complexes) localizes to the His-Purkinje system.

In general, atropine improves AV nodal conduction and carotid massage worsens it. These interventions typically have the opposite effect when AV block occurs in the His-Purkinje system. Atropine increases both atrial and ventricular rates in AV nodal block. Likewise, exercise (increased endogenous catecholamines) may reduce the extent of block. Precipitation of second-degree, high-grade, or complete AV block during exercise strongly suggests an infranodal site of block.

It is important to remember a few general rules to avoid common ECG misinterpretations of second-degree AV block. The 2:1 form of AV block may be nodal or infranodal. 2:1 block associated with narrow QRS complexes generally results from AV nodal block (Fig. 31.4). Wide QRS complexes are compatible with block in either the AV node or His-Purkinje system. If more than one P wave is not conducted to the ventricle, the term *high-grade AV block* is used (Fig. 31.5).

Complete AV block is diagnosed by the presence of independent atrial and ventricular activity on the ECG where the atrial rate is faster than the ventricular rate. When the atrial rhythm is sinus, AV dissociation is present, with the sinus rate exceeding the ventricular rate. The PP interval is constant. The RR interval is constant. The PR interval is variable in a random, nonrecurring pattern (Fig. 31.6). Complete AV block may also be present during all varieties of atrial tachycardia.

Complete AV block proximal to the His bundle results in a narrow QRS complex escape rhythm with rates of 50 to 60 beats per minute. Complete intra-His block may also result in a narrow QRS escape rhythm with ventricular rates less than or equal to 45 beats per minute.

Acquired complete AV block most commonly occurs distal to the His bundle, usually is secondary to a trifascicular conduction disturbance, is potentially life-threatening, and generally is irreversible. A wide QRS escape rhythm with ventricular rates less than 40 beats per minute is the rule. An exception is seen in the setting of inferior infarction, in which recovery of complete (narrow QRS) AV nodal block occurs in greater than 90% of patients (time to recovery 30 minutes to 16 days).⁵

Drug toxicity, coronary artery disease, and degenerative disease of the conduction system are the most common causes of AV block in adults. Surgery, electrolyte disturbances (such as hyperkalemia), endocarditis, myocarditis (Lyme carditis), tumors, myxedema, rheumatoid nodules, Chagas' disease, calcific aortic stenosis, polymyositis, amyloidosis, sarcoidosis, scleroderma, and vagotonic reflexes all may result in AV block. In truth, the number of factors and conditions that may result in AV block is nearly endless. "Hypervagal" responses (carotid hypersensitivity, neurocardiogenic syncope) may produce transient AV block (see later).³

Congenital complete AV block results from separation of the atrial musculature from the conduction system, or from nodoventricular disconnection. Mortality rate is highest in neonates, diminishes during childhood and adolescence, and then increases later in life. Patients may be asymptomatic for many years. It is difficult to predict prognosis in individual patients. Persistent ventricular rates less than 50 beats per minute correlate with the development of symptoms and syncope. Symptomatic patients and those patients with left ventricular dilatation should receive permanent pacemakers.

No reliable long-term pharmacotherapy exists for AV block. Transient AV nodal block may be managed with atropine. Infranodal block may be managed with (carefully titrated) isoproterenol until temporary or permanent pacing is established.

Figure 31.6 Complete heart block. The P waves and QRS complexes are regular, but they are not associated with one another.

JUNCTIONAL RHYTHM

When the sinus node does not depolarize the atrium for any reason (high vagal tone, SND), the cells near the AV junction (AV node, His bundle) may take over as the active pacemaker. Retrograde activation of the atrium, commonly manifest as negative P waves in the inferior leads (II, III, aVF), may be seen (Fig. 31.7). If the junctional rhythm goes faster than 60 beats per minute, it is termed an *accelerated junctional rhythm*. This is a common manifestation of digitalis toxicity.

VAGALLY MEDIATED SINUS ARREST, BRADYCARDIA, AND HEART BLOCK

The most common cause of nonconducted P waves during telemetry or Holter recordings is bradycardia-associated AV block. This manifests as sudden (usually nocturnal) block of one or more P waves with or without antecedent PR prolongation. This phenomenon is characterized by PP prolongation before AV block and is the result of transient increases in vagal tone. Vagally mediated sinus arrest, bradycardia, and heart block often occur in the intensive care unit (ICU) setting as a result of suctioning, gagging, femoral vessel compression (for hemostasis), and a variety of other triggers (Box 31.1). Vagal stimulation may lower blood pressure with or without significant bradycardia. Bradyarrhythmias and hypotension usually resolve when vagal stimulation ceases.

Box 31.1 Triggers for Vagally Mediated Heart Block

- Gagging reflexes such as with intubation or placement of a nasogastric tube
- Endotracheal suctioning and irrigation of the carina
- Distention of a visceral organ such as during colonoscopy or bladder irrigation
- Increased intrathoracic pressure as may occur with coughing or excessive tidal volumes on the ventilator
- Direct stimulation of the carotid body, which may occur with vascular surgery in this area
- Increased intracranial pressure and certain neurologic procedures
- Manual compression during femoral artery line removal
- Seizure-related
- Neurocardiogenic syncope or simple fainting in patients undergoing painful procedures or possibly in visitors to the intensive care unit

Figure 31.7 Junctional rhythm with retrograde P waves that are negative in the inferior leads.

Persistent bradycardia or hypotension mediated by vagal tone may require placing the patient in the Trendelenburg position, temporary saline infusion, or intravenous administration of atropine to fully resolve the episode.

SUPRAVENTRICULAR TACHYCARDIA

OVERVIEW

Tachyarrhythmias often occur in critically ill patients. Conditions such as hypoxemia, electrolyte imbalance, catecholamine excess (endogenous and exogenous), and other metabolic disturbances predispose patients (with or without preexisting arrhythmic substrates) to tachyarrhythmias. Intensivists must be prepared for acute management of supraventricular tachycardia. Knowledge of arrhythmia mechanisms, appropriate choices for acute pharmacotherapy, and indications for urgent or emergent direct current cardioversion are requisite.⁶ We will discuss the mechanisms of supraventricular tachyarrhythmias, give an ECG-guided approach to their diagnosis, and cover specific treatments for these dysrhythmias (pharmacologic and catheter ablation).

The substrate for most supraventricular tachycardias is present before ICU admission. Notable exceptions include atrial fibrillation (and flutter) after open-heart surgery and multifocal atrial tachycardia (MAT) (which may be transient, requiring no chronic therapy). Conditions such as hypoxemia, electrolyte imbalance, catecholamine excess (endogenous and exogenous), and other metabolic disturbances predispose patients (with or without preexisting arrhythmic substrates) to tachyarrhythmias.

PREMATURE ATRIAL CONTRACTIONS

Premature atrial, junctional, or ventricular beats are common in patients with or without structural heart disease and rarely result in significant alteration of cardiac output. They may occur as a result of enhanced sympathetic tone, metabolic stress, pericarditis, or direct mechanical irritation (as occurs with intracardiac catheters) and may result from the stimulant effects of caffeine, alcohol, intravenous inotropic support, or illicit drugs (such as cocaine). Atrial premature beats may be associated with aberrant conduction and confused with premature ventricular beats, or they may block in the AV node, creating a pause that may be confused with sinus arrest or SA exit block. Atrial premature beats may initiate reentrant supraventricular tachycardias or atrial fibrillation. Premature atrial contractions rarely require treatment, unless they trigger sustained supraventricular tachyarrhythmias.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

Five types of paroxysmal supraventricular tachycardia (PSVT) are recognized: (1) AV nodal reentry tachycardia (AVNRT); (2) AV reentrant tachycardia (AVRT); (3) intra-atrial reentry; (4) automatic atrial; and (5) sinus node reentry. First-line chronic therapy for most supraventricular tachycardias is catheter ablation. The following

discussion of therapy will be limited to acute pharmacologic management.

AVNRT is by far the most common and in the past accounted for 50% to 60% of PSVTs evaluated at referral centers.⁷ The precise reentrant circuit is not defined; however, it is clear that the anterior and posterior AV nodal approaches and the perinodal atrial tissue are involved. In 76% to 90% of cases, antegrade conduction proceeds along the posterior (slow) AV nodal approach (pathway) and retrograde conduction along the anterior (fast) AV nodal pathway.^{7,8} This is slow-fast AVNRT. Because retrograde conduction is so rapid, atrial and ventricular activation are virtually simultaneous. P waves are usually not visible on the surface ECG or may appear in the terminal portion of the QRS complex (pseudo R' in lead V₁ or pseudo-S waves in the inferior leads). Atrial contraction on a closed AV valve may produce neck pounding.⁹ Less common (so-called "unusual") variants (fast-slow, slow-slow, and slow-sort of slow) of AV nodal reentry also exist.⁸

AVNRT usually manifests after the age of 20 years⁸ and is more common in women than in men. The typical heart rate in AVNRT ranges from 150 to 250 beats per minute. Palpitations, lightheadedness, and near-syncope may accompany an episode. True syncope is unusual. Neck pounding (see previously) is virtually pathognomonic,⁸ but its absence does not exclude AVNRT.

Before catheter-based cures became routine, AVRT was the next most common (accounting for 30%) PSVT mechanism.⁷ AVRT (also commonly referred to as orthodromic tachycardia) manifests (on average) at a somewhat earlier age than that typical for AVNRT. The antegrade limb of the circuit proceeds down the normal AV nodal His-Purkinje system. The retrograde limb uses an accessory pathway that usually is located along the mitral or tricuspid valve annulus. Because the accessory pathway conducts in only retrograde fashion, it is concealed (not seen on surface ECG).

Because AVRT proceeds normally antegradely, the QRS complex is generally narrow. The AVRT reentry circuit travels antegradely through the AV node and His-Purkinje system to the ventricles before retrograde activation of the atria occurs via the bypass tract. The extra time taken to travel by way of the ventricles creates a longer RP interval during tachycardia compared with that seen in AVNRT. Because AVNRT and AVRT activate periannular atrial tissue first, P waves (if visible on surface ECG) will be negative in the inferior leads. Upright P waves in these leads indicate atrial (or sinus) tachycardia. AVRT tends to go faster than AVNRT and is more prone to manifest with QRS alternans or left bundle branch block (LBBB) aberrancy.^{10,11} A decrease in tachycardia rate on development of bundle branch block ipsilateral to the pathway is characteristic of AVRT. AV block is unusual during AVNRT and *excludes* the diagnosis of AVRT (which requires both atrial and ventricular participation). The presence of AV block strongly suggests the diagnosis of atrial tachycardia.

In the past, intra-atrial reentry, automatic atrial tachycardia, and sinus nodal reentry accounted for the remaining 8% to 10% of PSVTs.⁷ Sinus node reentry rarely occurs as an isolated phenomenon.¹²

Approximately 50% of patients with intra-atrial reentry have evidence of structural heart disease.¹³ This tachycardia is particularly prone to develop after surgery for congenital

cardiac anomalies. Reentry occurs around structural barriers, such as suture lines. In patients without clear-cut structural disease, subtle changes such as scarring and fibrosis provide the substrate for reentry. Automatic atrial tachycardias occur along the crista terminalis, near the ostium of the coronary sinus, along the tricuspid and mitral annulus, in both atrial appendages, and within or in close proximity to the pulmonary veins. Automatic atrial tachycardias are exquisitely sensitive to catecholamines. Although these tachycardias may manifest in the absence of structural heart disease or obvious precipitants, they also are commonly associated with chronic lung disease, pneumonia, myocardial (atrial) infarction, and acute alcoholic binges. Amphetamine or cocaine abuse also may precipitate automatic atrial tachyarrhythmias.

Reentrant atrial tachycardias tend to be paroxysmal, whereas automatic forms are more likely to be incessant. In both, atrial rates less than 200 beats per minute are characteristic. Persistent elevation of the ventricular rate may result in a (reversible) tachycardia-mediated cardiomyopathy.

As noted, the presence of AV block during tachycardia provides strong evidence that the rhythm disturbance is atrial in origin. Negative P waves are not helpful in differentiating atrial tachycardia from AVNRT or AVRT. An inferior P wave axis with a negative P in lead I is diagnostic of left atrial tachycardia. An inferior P axis, a positive P in lead I, and a P wave morphology different from sinus rhythm can result only from atrial tachycardia.

Sinus node reentry may occur within the sinus node, the perinodal atrial tissue, or both. Although the mechanism may be difficult to prove clinically, most investigators agree that the P wave may be *nearly* identical to sinus rhythm, suggesting that the reentrant exit point may differ slightly from sinus pacemaker beats. Average rates generally are 130 to 140 beats per minute (range 80 to 200).

APPROACH TO PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA THERAPY

Acute management of PSVT should begin with attempts to slow or (transiently) interrupt AV nodal conduction. Vagal maneuvers (such as carotid sinus massage or Valsalva) may be tried first. Adenosine is the initial drug of choice for acute management of PSVT. An initial intravenous dose of 6 mg may be followed (2 minutes) later by 6 mg (if necessary), and 12 mg may be given (2 minutes) later if 6 mg is unsuccessful.

Adenosine should terminate more than 90% of AVNRT and AVRT. This agent also is effective in sinus node reentry. Adenosine also may terminate automatic atrial tachycardias, particularly those originating near the crista terminalis, where vagal innervation is rich. Termination may be transient because of adenosine's short half-life (10 seconds).

Intravenous verapamil (5 to 10 mg is injected over a period of 30 seconds, followed by an additional 5 mg, if necessary, after a 5- to 10-minute interval) or diltiazem (0.25 mg/kg, followed by an additional dose of 0.35 mg/kg, if necessary, after a 15-minute interval) usually is effective for PSVT termination when adenosine fails. AV block without arrhythmia termination (again) suggests the diagnosis of atrial tachycardia. Because of their longer half-lives,

intravenous calcium channel blockers also may be effective for treatment of prompt tachycardia recurrence after initial success with adenosine.

Automatic atrial tachycardia is difficult to manage with pharmacotherapy. Precipitants should be treated or eliminated whenever possible. Beta blockers may slow atrial rate but rarely restore sinus rhythm. Adenosine may produce sinus rhythm; however, tachycardia may resume as soon as the drug is metabolized.¹⁴ Vagal maneuvers may produce AV block but do not terminate these arrhythmias. Clinical successes have been obtained with class IC agents and amiodarone. Flecainide should be avoided in patients with coronary artery disease or significant left ventricular dysfunction. Intravenous flecainide is not available in the United States (see later). Amiodarone is available for intravenous administration. Intravenous amiodarone may result in hypotension (vasodilation) but usually does not exacerbate heart failure or cause proarrhythmia in the setting of preexisting left ventricular dysfunction.

Sinus node reentry may respond to vagal maneuvers, adenosine, verapamil, and digitalis (relatively slow onset of action limits acute application). Acute management of intra-atrial reentry is similar to that for atrial fibrillation in the absence of antegrade accessory pathway conduction (see later). Emergent or urgent direct current cardioversion is indicated when PSVT results in angina pectoris, congestive heart failure (CHF), or hypotension. Techniques for and limitations of direct current cardioversion are discussed later in the chapter. Automatic tachycardias (including MAT) do not respond to direct current cardioversion.

WOLFF-PARKINSON-WHITE SYNDROME AND ITS VARIANTS

The ECG pattern of Wolff-Parkinson-White syndrome (see “[Electrocardiographic Patterns Intensivists Should Recognize](#)”), short PR interval with preexcitation (delta wave), has a reported prevalence of 0.1% to 0.3% in the general population. It is twice as common in men as in women.

Classic Wolff-Parkinson-White syndrome occurs when the accessory AV pathway is capable of bidirectional conduction (AV and ventriculoatrial). Symptomatic presentation usually is during the teenage years or early adulthood. Pregnancy may exacerbate symptoms. The most common tachycardia is AV reentry (down the AV node and His-Purkinje system, up the bypass tract), identical to AVRT involving a concealed bypass tract. Approximately 25% of patients with a Wolff-Parkinson-White ECG pattern are incapable of retrograde conduction via the accessory pathway (and therefore do not have orthodromic AVRT). Asymptomatic patients generally have a benign prognosis; however, the initial presentation may be ventricular fibrillation (see later).¹⁵

Accessory pathways generally have conduction properties similar to those of myocardium. Decremental conduction, (AV conduction delay or block) which is characteristic of the AV node, is uncommon. Pathways may therefore be capable of very rapid antegrade (AV) conduction. In these instances, atrial fibrillation may be associated with irregular wide QRS tachycardia and ventricular rates in excess of 300 beats per minute (Fig. 31.8). Syncope or SCD (degeneration to ventricular fibrillation) may ensue. Intravenous ibutilide (1 mg infused over 10 minutes; a second 1-mg dose may be

Figure 31.8 A 12-lead electrocardiogram (ECG) tracing from a patient with Wolff-Parkinson-White syndrome showing preexcited atrial fibrillation with rapid ventricular response. A rapid, “irregularly irregular” wide QRS tachycardia is present. Preexcited atrial fibrillation, as seen here, may degenerate to ventricular fibrillation. This ECG pattern should be promptly recognized by all practicing clinicians. I, II, III aVR, aVL, aVF, and V₁ to V₆ designate surface ECG leads. (From Trohman RG: Supraventricular tachycardia: Implications for the intensivist. Crit Care Med 2000;28(Suppl 10):N129-N135.)

given by infusion after a 10-minute wait, if necessary) also blocks antegrade accessory pathway conduction and is more likely to terminate acute episodes of atrial fibrillation or flutter (see later).¹⁶

Regular wide QRS tachycardia in patients with Wolff-Parkinson-White syndrome may have any of several mechanisms. Aberrancy resulting from right or LBBB (fixed or functional) may occur during orthodromic AVRT. As noted, bundle branch block ipsilateral to the accessory pathway may slow the tachycardia rate.

Antidromic tachycardia occurs when antegrade conduction proceeds via a free-wall accessory pathway, and retrograde conduction occurs over the normal His-Purkinje–AV nodal route. The ventricles are activated eccentrically beginning at the insertion of the accessory pathway. The resulting maximally preexcited wide QRS rhythm may be difficult to distinguish from ventricular tachycardia.

Although accessory pathways may be located anywhere along the AV groove, two variants with characteristic locations deserve mention. Paroxysmal junctional reciprocating tachycardia (PJRT) is a form of AV reentry that may be nearly incessant. The antegrade limb of the circuit is the normal AV conduction system. The retrograde limb is a concealed, decrementally conducting accessory pathway usually located posteroseptally. As noted earlier, incessant tachycardia may result in a tachycardia-mediated cardiomyopathy.

Atriofascicular pathways (Mahaim fibers) connect the right atrium and the right bundle branch. During sinus rhythm, preexcitation is minimal or absent. Typical Mahaim

reentry travels antegradely down the bypass tract and retrogradely through the normal conduction system (usually beginning with the right bundle branch). A regular wide QRS typical LBBB pattern is seen.¹⁷ These pathways conduct antegrade in a decremental fashion (retrograde accessory pathway conduction is absent) and occur much less frequently than typical AV accessory pathways. Patients with atriofascicular fibers frequently have multiple accessory pathways or AVNRT.^{15,18}

ACUTE MANAGEMENT OF TACHYCARDIA ASSOCIATED WITH WOLFF-PARKINSON-WHITE SYNDROME

Acute tachycardia treatment depends on characteristics of its QRS complexes. A 12-lead ECG should be obtained whenever possible.

Orthodromic AVRT usually manifests with a narrow QRS complex (functional or fixed bundle branch block can widen the QRS). Treatment should begin with vagal maneuvers. If these do not terminate the tachycardia, intravenous adenosine is the initial drug of choice. These therapeutic interventions interrupt AVRT by creating transient AV nodal conduction block.

Treatment of wide QRS tachycardia should be directed at blocking conduction via the accessory pathway. Adenosine may terminate antidromic tachycardia (at the AV node), but it will not affect atrial tachyarrhythmias conducting rapidly across the accessory pathway. Because of its short half-life adenosine administration poses little risk, unless it precipitates atrial fibrillation.

Intravenous verapamil is contraindicated in the presence of wide QRS tachycardia. Its hypotensive effects may make patients hemodynamically unstable and contribute to the onset of ventricular fibrillation. Intravenous digoxin is not given to patients with Wolff-Parkinson-White syndrome and atrial fibrillation because it may (in approximately one third of patients) enhance antegrade accessory pathway conduction and may result in degeneration to ventricular fibrillation.

Patients whose supine systolic blood pressure is greater than 90 mm Hg can be given intravenous adenosine. It is administered in the same manner as described previously. Tachycardia termination suggests a supraventricular mechanism that includes the AV node as a requisite part of the circuit. Transient AV block suggests an atrial tachycardia. No response to adenosine suggests a ventricular origin.^{19,20}

Direct current cardioversion should be available, preferably at the bedside, whenever treatment of a wide QRS tachycardia is undertaken. If, at baseline, the patient exhibits signs of hemodynamic compromise (angina, heart failure, or hypotension), drug therapy should be eschewed and direct current cardioversion employed to promptly restore sinus rhythm. If hemodynamic instability develops during drug therapy, direct current cardioversion should be performed immediately. Direct current cardioversion also should be the next elective therapy when pharmacotherapy is unsuccessful.

NONPAROXYSMAL ATRIOVENTRICULAR JUNCTIONAL TACHYCARDIA, PAROXYSMAL ATRIAL TACHYCARDIA WITH BLOCK, AND AUTOMATIC ATRIOVENTRICULAR JUNCTIONAL TACHYCARDIA

Nonparoxysmal AV junctional tachycardia occurs primarily in the setting of digitalis toxicity. It also is associated with cardiac surgery, myocardial infarction, and rheumatic fever. Hypokalemia may cause or exacerbate this arrhythmia. Sympathetic stimulation increases the tachycardia rate.

Digitalis toxicity also may precipitate atrial tachycardia (so-called paroxysmal atrial tachycardia with block) (Fig. 31.9). This tachycardia usually is managed by withholding digoxin and administering potassium. Lidocaine, phenytoin, and digoxin-specific antigen-binding fragments also may be used.

Automatic AV junctional tachycardia, also known (particularly in pediatrics) as junctional ectopic tachycardia,

Figure 31.9 Atrial tachycardia with second-degree type I (Wenckebach) atrioventricular (AV) block. Atrial tachycardia with block can be seen in digitalis toxicity. In this example, second-degree type 1 AV block is seen. Atrial tachycardia or atrial fibrillation with complete heart block. The arrows show the P waves. (From Surawicz B, Knilans T: Chou's Electrocardiography in Clinical Practice: Adult and Pediatric, 6th ed. St. Louis, Elsevier, 2008.)

primarily affects children and infants. It often is incessant. In patients without congenital heart disease, it may manifest as a tachycardia-mediated cardiomyopathy.

This tachyarrhythmia results in marked hemodynamic deterioration after corrective surgery for congenital heart disease. It generally appears within 12 hours postoperatively and terminates within a few days if the patient survives. Digitalis, beta blockers, and class IA antiarrhythmics are ineffective in children. Amiodarone (which may suppress tachycardia or control its rate) should be administered when rates less than 150 beats per minute cannot be achieved by other means.²¹ In adults, beta blockade may successfully control the rate. Adult automatic AV junctional tachycardia may be difficult to manage medically (Fig. 31.10). Recent reports suggest that catheter ablation can eliminate tachycardia while preserving AV conduction.²²⁻²⁴

MULTIFOCAL ATRIAL TACHYCARDIA

MAT is an automatic tachyarrhythmia. It is characterized by three or more morphologically distinct (nonsinus) P waves, atrial rates of 100 to 130 beats per minute, and variable AV block (Fig. 31.11).

MAT is commonly associated with respiratory disease and CHF. It has been reported in patients with cancer, lactic acidosis, pulmonary emboli, renal disease, and infection. Hypoxemia frequently is present. MAT may be exacerbated by digitalis or theophylline toxicity, hypokalemia, hypomagnesemia, and hyponatremia. These precipitants usually do not result in MAT if respiratory decompensation is absent. Although MAT is (in general) an uncommon arrhythmia, it is relatively common in the critical care setting. Treatment

Figure 31.10 Atrioventricular (AV) junctional tachycardia. This rhythm strip demonstrates short bursts of tachycardia. The fifth and eighth beats are preceded by discernible P waves and are likely sinus in origin. AV junctional tachycardia can be difficult to manage medically. (From: Trohman RG, Haery C, Pinski SL: Focal radiofrequency catheter ablation of an irregularly irregular supraventricular tachycardia. Pacing Clin Electrophysiol 1999;22:360-362.)

Figure 31.11 Multifocal atrial tachycardia is characterized by three or more morphologically distinct (nonsinus) P waves, atrial rates of 100 to 130 beats per minute, and variable atrioventricular block. Note the irregularity of the rhythm as well as the different P wave morphologic appearances (arrows) with different PR intervals.

of MAT usually is directed at elimination of the underlying precipitants. Metoprolol (used cautiously when bronchospasm is present) or verapamil may provide (atrial and ventricular) rate control and occasionally restore sinus rhythm.^{25,26} Potassium and magnesium supplements may help suppress MAT. Amiodarone has also been useful in restoring sinus rhythm. MAT may, superficially, resemble atrial fibrillation. Careful examination of a 12-lead ECG may be required to distinguish between these two entities. Differentiation is important for proper patient management. As noted, MAT does not respond to direct current cardioversion and is not amenable to catheter ablation.

SINUS TACHYCARDIA

Sinus tachycardia usually is a normal reflex response to changes in physiologic, pharmacologic, or pathophysiologic stimuli such as exercise, emotional upset, fever, hemodynamic or respiratory compromise, anemia, thyrotoxicosis, poor physical conditioning, sympathomimetic or vagolytic agents, and abnormal hemoglobins.²⁷ The resulting increase in cardiac output usually is beneficial. Heart rate generally does not exceed 180 beats per minute, except in young patients, who may achieve rates higher than 200 beats per minute during vigorous exercise.³ Tachycardia resolves when conditions return to baseline. The differential diagnosis for sinus tachycardia is presented in Table 31.1.

Sinus tachycardia is often present in ICU patients and sometimes is difficult to distinguish from other supraventricular tachycardias. When observed over time, sinus tachycardia will change its rate, with gradual acceleration and gradual deceleration. The P wave morphology of sinus tachycardia should be upright in leads I, II, aVF, and V₄ to V₆. Sinus tachycardia may slow transiently with vagal maneuvers or intravenous adenosine. If adenosine administration produces AV block, the P wave morphology can be clearly seen if a 12-lead ECG is run in rhythm strip mode. A negative P wave in (any of) leads I, II, aVF, and V₄ to V₆ excludes sinus tachycardia. P waves that are negative in lead I suggest a left atrial origin. Differentiation of “high” right atrial tachycardia waves from sinus tachycardia is more difficult. P-wave amplitude in the inferior leads may increase (normally) during sinus tachycardia. Comparison of the 12-lead P-wave morphology with that on an older 12-lead ECG tracing (if obtainable) when the patient was clearly in normal sinus rhythm may not result in an exact match.

ATRIAL FLUTTER

Although the precise reentrant circuit is unknown, typical atrial flutter traverses (with either counterclockwise or clockwise rotation) through an isthmus formed by the inferior vena cava, tricuspid valve, eustachian ridge, and coronary sinus ostia. Counterclockwise rotation is more common

Table 31.1 Differential Diagnosis of Sinus Tachycardia

Etiologic Category	Specific Disorders
Hemodynamic	Heart failure—systolic and diastolic heart failure caused by ischemic, valvular, or nonischemic myopathy
	Loss of circulating blood volume—gastrointestinal bleeding, anemia, shifts of intravascular fluid due to changes in colloidal osmotic pressure or inflammation
	Septic shock—dehydration
	Vascular shunts—intracardiac as well as aortovenous malformations, fistulas
	Pulmonary embolism
Metabolic and neurohumoral	Sepsis—infections and inflammatory conditions
	Hyperthyroidism
	Paget’s disease of the bone
	Pheochromocytoma
	Carcinoid syndrome
	Beriberi heart disease
	Carcinoma
	Hyperpyrexia
	Acidosis
	Exercise
Pharmacologic	Sympathomimetic agents—isoproterenol, epinephrine, or dopamine
	Vagolytic agents, atropine, acopolamine
	Vasodilators—nitrates, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, hydrazine, as well as centrally acting vasodilators
	Thyroid preparations, caffeine and nicotine
	Bronchodilators, including theophylline and terbutaline
	Anesthetic agents, including spinal anesthetics, causing peripheral vasodilation
	Drugs of abuse—amphetamines, cocaine, “ecstasy,” cannabis
	Pain
Neurologic/psychological	Fear, anxiety, and hysteria
	Hyper-beta adrenergic phase of neurocardiogenic syncope
	Autonomic dysfunction such as with diabetes

and results in negative “flutter” waves in ECG leads II, III, aVF, and V₆. Atrial activity in lead V₁ is positively directed. Clockwise atrial flutter produces oppositely directed flutter waves in these leads. Atrial rates generally range between 250 and 350 beats per minute; however, slower rates may be seen in the presence of specific pharmacotherapy (which slows conduction within the circuit) or marked right atrial enlargement (presumably caused by a larger circuit).²⁸ Atrial flutter usually manifests with 2:1 AV block and ventricular rates of approximately 150 beats per minute.

Pharmacotherapy for (typical and atypical) atrial flutter is similar to that outlined for atrial fibrillation. Special care must be taken to avoid inadvertent precipitation of 1:1 AV conduction and subsequent hemodynamic deterioration. Radiofrequency ablation is first-line curative therapy for typical atrial flutter.

ATRIAL FIBRILLATION

Atrial fibrillation is the most important sustained supraventricular arrhythmia both in frequency and in potential for long-term sequelae. Atrial fibrillation and atrial flutter frequently coexist. More than 2 million people in the United States suffer from atrial fibrillation and this number is expected to rise as the population ages. The frequency of this arrhythmia increases dramatically after the age of 60.

Atrial fibrillation most often is associated with structural cardiac (diffuse atrial) disease. Unlike in typical atrial flutter, left atrial enlargement is more important than right atrial enlargement in the pathogenesis of atrial fibrillation.²⁹ The chaotic ECG appearance of this arrhythmia usually is the result of shifting reentrant circuits (multiple wavelet hypotheses). Atrial fibrillation may have focal triggers (usually in one or more pulmonary veins).³⁰ Causes of atrial fibrillation are listed in [Box 31.2](#).

ACUTE MANAGEMENT OF ATRIAL FIBRILLATION

Treatment of atrial fibrillation has three important components: (1) ventricular rate control; (2) restoration (and maintenance) of sinus rhythm; and (3) prevention of embolic phenomena.

Although atrial fibrillation is the most common sustained arrhythmia, there is no consensus on optimal atrial fibrillation management. In the critically ill, atrial fibrillation may be a “sign” (perhaps of disease severity) rather than an arrhythmic disease entity (as seen in noncritically ill patients with recurrent paroxysmal, persistent, and permanent atrial fibrillation). Critically ill patients are often in a hyperadrenergic state, which may increase ectopic triggers and shorten atrial refractoriness. This is likely the mechanism of atrial fibrillation in younger patients without chronic structural heart disease. In older patients with structural disease, increased adrenergic tone (and triggers) may precipitate atrial fibrillation when fibrosis has already created a suitable reentrant substrate.³¹

A logical approach to atrial fibrillation in the ICU requires the answers to the following questions:

1. Is the diagnosis of atrial fibrillation correct?
2. Are there causes/precipitants (see [Box 31.2](#)) that can be eliminated or corrected?
3. Is it necessary to restore and maintain sinus rhythm?

Box 31.2 Causes of Atrial Fibrillation

Increased atrial pressure, secondary to:

- Mitral or tricuspid valve disease
- Myocardial disease (primary or secondary, leading to systolic or diastolic dysfunction)
- Semilunar valve abnormalities (causing ventricular hypertrophy)
- Intracardiac tumors or thrombi

Atrial ischemia

- Coronary artery disease

Inflammatory or infiltrative atrial disease

- Pericarditis
- Amyloidosis
- Myocarditis

Age-induced atrial fibrotic changes

Intoxicants and toxins

- Alcohol
- Carbon monoxide
- Poison gas

Increased sympathetic activity

- Hyperthyroidism
- Pheochromocytoma
- Anxiety
- Alcohol
- Caffeine
- Drugs

Increased parasympathetic activity

Primary or metastatic disease in or adjacent to the atrial wall

Postoperative causes

- Cardiac and pulmonary surgery
- Overhydration
- Pericarditis
- Cardiac trauma
- Hypoxia
- Pneumonia

Congenital heart disease

- Particularly atrial septal defect

Neurogenic causes

- Subarachnoid hemorrhage
- Nonhemorrhagic, major stroke

Idiopathic

From Falk RH, Podrid PJ (eds): *Atrial Fibrillation: Mechanisms and Management*. New York, Raven Press, 1992.

4. Is atrial fibrillation causing hemodynamic impairment (angina, heart failure, hypotension)?
5. What are the potential adverse effects of the various therapeutic options?³¹

It is important to carefully analyze a 12-lead ECG because, as previously noted, MAT may be misinterpreted as atrial fibrillation on a rhythm strip. The treatment of choice for MAT remains correction of precipitants such as hypoxemia, digitalis or theophylline toxicity, hypokalemia, or hypomagnesemia. Atrial fibrillation may, likewise, terminate (and be less likely to recur) when precipitants are removed or corrected.³¹

Atrial fibrillation that does not compromise the patient may not require aggressive therapy. Rate control strategies may suffice. Spontaneous atrial fibrillation termination may be difficult to distinguish from a clear-cut benefit of specific

antiarrhythmic pharmacotherapy. Hemodynamic impairment should be treated with urgent or emergent direct current cardioversion.³¹

Serial direct current shocks are not appropriate for recurrent (within hours or days) paroxysms (self-terminating episodes) of atrial fibrillation. This scenario is relatively common in ICUs or after cardiac surgery. It is also important to avoid repetitive, futile shocks or delivery of direct current to an inadequately sedated patient because both of these may heighten the hyperadrenergic state and create or exacerbate a downward clinical spiral.³¹⁻³³ Restoration of sinus rhythm may be very difficult and impractical when a *severe* metabolic derangement or multisystem organ failure is present.³²

Control of the ventricular rate (Table 31.2) is most frequently achieved using digoxin, beta blockers, calcium channel blockers (verapamil or diltiazem), or combinations of these agents. Verapamil should be administered cautiously to patients with significant left ventricular dysfunction. Although digoxin is effective in controlling rates at rest, exercise rate control is not often achieved. Digoxin remains appropriate therapy for patients with concomitant left ventricular dysfunction and CHF. Intravenous diltiazem is effective and well tolerated. Diltiazem may be administered by continuous intravenous infusion. The combination of efficacy, ease of parenteral delivery, and tolerance makes this agent an attractive option in the critical care setting.

A variety of agents may be used to restore sinus rhythm. Patients with adrenergically mediated atrial fibrillation should be managed initially with beta blockers. Sotalol and amiodarone are options in patients with atrial fibrillation refractory to beta blockade alone.

It has become relatively common to treat acute episodes with intravenous ibutilide. This unique class III agent

prolongs action potential by blocking the rapid component of the delayed rectifier current.^{34,35} This increase results in QT interval prolongation. Patients receiving intravenous ibutilide should be carefully monitored³⁴ (on telemetry for 4 to 8 hours) for development of torsades de pointes. Direct comparisons of intravenous procainamide and ibutilide have demonstrated clear superiority of ibutilide in conversion of atrial fibrillation and atrial flutter. Restoration of sinus rhythm with ibutilide occurred in 32% to 51% (atrial fibrillation) and 64% to 76% (atrial flutter) patients, compared with 0% to 5% (atrial fibrillation) and 0% to 14% (atrial flutter) after intravenous procainamide.^{34,36,37} As a result of this data, use of procainamide for this indication has become passé. Ibutilide is suitable for acute cardioversion; however, prolonged intravenous or oral dosing is not available to prevent arrhythmia recurrence. Ibutilide may be administered safely to patients on concomitant antiarrhythmic agents.³⁸

Intravenous amiodarone is (initially) primarily a calcium channel and beta blocker. It may be effective for rate control when other agents fail. The temptation to use intravenous amiodarone to restore sinus rhythm should be tempered by knowledge of its acute electrophysiologic effects. Its class I and, particularly, class III effects take time to occur, making this a poor choice for rapid conversion. Bolus treatment with intravenous amiodarone has been very disappointing (4% conversion) for acute conversion of atrial fibrillation. By contrast, in approximately 20% to 50% of patients with persistent atrial fibrillation (lasting longer than 24 to 48 hours), reversion to sinus rhythm is achieved with sustained administration (loading periods of up to 4 weeks) of oral amiodarone.³⁹ Intravenous amiodarone may result in less hypotension when used for rate control in the ICU than diltiazem.^{40,41}

Table 31.2 Intravenous Drugs for Atrial Fibrillation

Drug	Acute Dose	Maintenance Dose	Comments
Drugs for Rate Control^[‡]			
Digoxin	1 mg over 24 h in increments of 0.25-0.5 mg	0.125-0.25 mg	Not very effective in high-catecholamine states; caution with renal disease
Esmolol [†]	0.5 mg/kg/min for 1 min	0.05-0.2 mg/kg/min	Short half-life; hypotension common
Verapamil	5-20 mg in 5-mg increments	5 to 10-mg boluses every 30 min or 0.005 mg/kg/min	Caution with left ventricular dysfunction
Diltiazem	20-25 mg or 0.25-0.35 mg/kg	10-15 mg/h	Well tolerated; may cause hypotension
Drugs for Cardioversion			
Procainamide	10-15 mg/kg at ≤50 mg/min	2-6 mg/min	May cause hypotension
Amiodarone [‡]	150 mg over 10 min, then 1 mg/min for 6 h	0.5 mg/min	May cause hypotension; many long-term side effects
Ibutilide	1 mg over 10 min A second dose may be given 10 min after the first	None	Prolongs QT; may cause torsades de pointes May lower energy requirement for direct current cardioversion

Adapted from Falk RH: Control of the ventricular rate in atrial fibrillation. In Falk RH, Podrid PJ (eds): Atrial Fibrillation: Mechanisms and Management. New York, Raven Press, 1992.

*Assumes no preexcitation.

[†]Metoprolol and propranolol also may be used.

[‡]Amiodarone also is effective for rate control.

Intravenous class IC agents (such as flecainide and propafenone) are the most effective drugs for converting atrial fibrillation of recent onset. Unfortunately, they are not available in the United States. Ibutilide is more effective than intravenous class IC agents for restoration of sinus rhythm in atrial flutter.³⁹ Electrical cardioversion remains the most effective way of restoring sinus rhythm in patients with atrial fibrillation. As noted, urgent electrical cardioversion should be contemplated for sustained tachycardias that precipitate angina, heart failure, or hypotension.

There are many pitfalls associated with acute atrial fibrillation management. Intravenous beta and calcium channel blockers may result in bradycardia, hypotension, and heart failure. Beta blockers may also aggravate or precipitate bronchospasm. Ibutilide may be proarrhythmic (torsades de pointes). Amiodarone is unlikely to be proarrhythmic in the absence of electrolyte abnormalities (hypokalemia, hypomagnesemia) or other drugs that have already prolonged the rate-corrected QT interval (QTc).^{31,34,41}

In the absence of clear-cut evidence from randomized controlled trials, appropriate management should include treatment (or elimination) of potential precipitants and beta blockade (given the hyperadrenergic state of many ICU patients) as the initial pharmacotherapy of choice. If atrial fibrillation recurrence needs to be prevented and sinus rhythm maintained, institution of specific antiarrhythmic therapy (intravenous procainamide, intravenous or oral amiodarone, oral dofetilide, or sotalol) may be effective. We favor adding intravenous amiodarone. This recommendation is based on 100% bioavailability of the intravenous preparation (critically ill patients may not absorb oral drugs), amiodarone's noncompetitive β -antagonistic effects, its benefit in the perioperative period of cardiac surgery⁴² (a time when endogenous and exogenous catecholamine levels are often high), and its efficacy in preventing atrial fibrillation recurrence.^{31,41}

A recent meta-analysis of perioperative prophylactic amiodarone demonstrated decreased incidence of atrial fibrillation and flutter, ventricular tachyarrhythmias, stroke, and reduced length of stay after cardiac surgery.⁴² Not all studies included used beta blockade, and the course of therapy was inconsistent among trials. The Prophylactic Oral Amiodarone for the Prevention of Arrhythmias That Begin Early after Revascularization, Valve Replacement, or Repair (PAPABEAR), a large randomized controlled trial, compared perioperative amiodarone with placebo and showed significant reduction in postoperative atrial tachyarrhythmias.⁴³ Toxicity risks were reduced because amiodarone was used for a short duration. Neither study demonstrated reduction in mortality rates. The data for perioperative amiodarone in cardiac surgery are compelling; however, incremental benefit beyond beta blockade alone remains unclear. It may still be reasonable to reserve amiodarone for postoperative atrial fibrillation in patients already receiving beta blockers and to limit use of amiodarone to 6 to 12 weeks postoperatively to prevent side effects.

Special Considerations for the Intensivist

As noted, patients in an intensive care setting frequently have active precipitants for reinitiation of atrial or ventricular arrhythmias. Such factors include hypoxemia, excess circulating (endogenous and exogenous) catecholamines,

CHF, fever (sepsis), and pulmonary emboli, etc. Many of these conditions have overlapping features.

Digoxin, procainamide, dofetilide, and sotalol are excreted renally and must be carefully managed (or avoided) to prevent complications in patients with renal failure or insufficiency. Amiodarone is hepatically excreted and can be used safely in patients with renal insufficiency or renal failure on dialysis.

Prophylaxis against arrhythmia recurrence shares many of the limitations of acute therapy. Drugs administered orally may not be well absorbed, and intravenous agents (procainamide and amiodarone) may cause or exacerbate hypotension. These factors conspire to make prophylaxis against recurrence difficult.

Most digitalis toxicity-related supraventricular arrhythmias result in relatively slow heart rates and are reasonably well tolerated hemodynamically. Accelerated junctional rhythm and paroxysmal atrial tachycardia with block tend to terminate spontaneously after digoxin is stopped. Digitalis toxic ventricular tachycardia (classically bidirectional tachycardia) is more serious but often slow and hemodynamically well tolerated. Dilantin and lidocaine may be effective for control of digitalis-induced ventricular tachycardia. Digoxin antibodies can be used in cases in which watchful waiting or lidocaine is ineffective or ventricular tachycardia is poorly tolerated due to hemodynamic instability. Electrical cardioversion is contraindicated in the presence of digitalis toxicity. Refractory ventricular fibrillation may ensue.

The intensivist must balance complicated issues before undertaking direct current cardioversion. Strong effort should be focused on avoidance of low-yield attempts. Repeated doses of anesthesia and multiple shocks will ultimately result in further deterioration of critically ill patients. Optimal management of precipitants, careful choices, and monitoring of antiarrhythmic therapy, as well as a solid understanding of cardioversion and defibrillation techniques (see later), will maximize success. In some cases of atrial fibrillation, rapid ventricular rate cannot be controlled by pharmacotherapy. Radiofrequency ablation of the AV junction and permanent pacing may be required when medical therapy is ineffective.⁴⁴

Anticoagulants for Stroke Prevention in Atrial Fibrillation. Prevention of embolic strokes remains the most important goal of therapy for atrial fibrillation. Anticoagulation plays a pivotal role in minimizing the risk of emboli (and strokes) during elective cardioversion of atrial fibrillation.⁴⁵ Classic recommendations for management of atrial fibrillation of more than 48 hours' duration include 3 weeks of therapeutic warfarin (to achieve a prothrombin time [PT]/international normalized ratio [INR] of 2.0-3.0) before direct current shock administration and (at least) 4 more weeks of warfarin after the procedure. Although emboli may be less frequent with atrial flutter,⁴⁵ it is clear that they occur,⁴⁶ and the recommendations are the same as for atrial fibrillation. Novel oral anticoagulants have recently been introduced for stroke prophylaxis in atrial fibrillation (see later).

Anticoagulation in the ICU. The intensivist rarely sees ideal candidates for classic anticoagulation. Outpatient

preparation for an elective cardioversion would be an exception rather than the rule. Likewise, the intensivist sees many patients with recent or active bleeding (gastrointestinal, intracerebral) and a variety of coagulopathies that make anticoagulation absolutely or relatively contraindicated.

Short-term therapeutic anticoagulation with heparin before cardioversion (followed by warfarin in the usual manner) combined with transesophageal echocardiography (TEE) has gained acceptance as an alternative approach.⁴⁷ Data from the ACUTE trial suggested similar embolic rates (0.5% versus 0.8%) comparing conventional and TEE-guided approaches.⁴⁸

TEE is useful for detecting left atrial thrombi. It provides an excellent, minimally invasive view of the left atrial appendage. Patients with obvious thrombi should be anticoagulated for up to 8 weeks and have demonstrable resolution of clot before cardioversion is attempted.⁴⁷

The intensivist must carefully weigh the risks and benefits of anticoagulation for each individual patient. Difficult decisions about the safety of both short- and long-term anticoagulation may be compounded by concomitant disease processes. At times, TEE may be the only possible (partial) insurance against emboli. Negative results on TEE, however, do not constitute a guarantee against emboli, and the temptation to routinely substitute TEE for adequate anticoagulation should be avoided.

There are well-described risk factors that help the clinician balance the risk of anticoagulation and the risk of stroke from atrial fibrillation. The CHADS₂ and CHA₂DS₂-VASc (Congestive heart failure, Hypertension, Age \geq 75 years [doubled risk weight], Diabetes mellitus, previous Stroke/transient ischemic attack [doubled risk weight], Vascular disease, Age 65 to 74 years, female Sex) risk scores as well as a novel bleeding risk score, HAS-BLED (Hypertension, Abnormal renal/liver function, Stroke history, Bleeding history or predisposition, Labile international normalized ratio, Elderly [\geq 65 years], Drugs/alcohol concomitantly) aid the clinician in balancing a patient's embolic stroke risk with the risk for bleeding.⁴⁹ Patients who are younger than age 65 years with normal hearts and "lone" atrial fibrillation (i.e., with none of the aforementioned risk factors) can be anticoagulated with aspirin 325 mg daily or perhaps not at all. Patients with 1 point should have individualized treatment, and patients with 2 points should be anticoagulated. Patients with rheumatic mitral stenosis or the presence of a prosthetic heart valve are among the highest risk for stroke and should be anticoagulated regardless of the CHADS₂ score.⁵⁰

Until the last several years, warfarin has been the only oral anticoagulant used and approved for stroke prophylaxis in atrial fibrillation (as well as anticoagulation for mechanical heart valves and venous thromboembolism). Although warfarin has been proved effective, the need for frequent INR monitoring and its many interactions with other drugs and foods have made this agent cumbersome to use.

Recently, two classes of drugs, the direct thrombin (factor IIa) inhibitors and the factor Xa inhibitors (collectively termed "novel anticoagulants") have emerged as options for prophylaxis against stroke in patients with nonvalvular atrial fibrillation. As a majority of patients in atrial fibrillation are willing to consider switching to these medications,

intensivists will undoubtedly encounter patients on these drugs and deal with issues that arise from their use.⁵¹

Dabigatran, a direct thrombin inhibitor, is an oral anticoagulant dosed twice a day. The drug was studied in comparison to warfarin for reduction of strokes in patients with atrial fibrillation. The RE-LY trial found a decreased incidence of stroke with the 150 mg dose of dabigatran and similar risk of bleeding.⁵² Dabigatran's half-life is 14 to 18 hours and it is recommended that it be stopped 2 to 3 days prior to an elective surgery (4 to 5 days seems more prudent). There is no specific antidote to this drug. Local measures may suffice for minor bleeding. Dialysis and dabigatran's relatively short half-life usually allow discontinuation of the drug to reverse the bleeding diathesis. The only current reversal option for dabigatran is emergency dialysis. Performing dialysis rapidly in unstable patients with bleeding or in those with large intracranial hemorrhage will present a very great challenge, even at level 1 trauma centers.⁵³

In addition to thrombin (factor IIa), the coagulation factor Xa is a target for the novel anticoagulants. In the United States rivaroxaban and apixaban are approved for the treatment of atrial fibrillation, and additional drugs are being studied. The ROCKET-AF trial demonstrated that the once-daily drug rivaroxaban was noninferior to warfarin in reducing strokes with similar bleeding rates.⁵⁴ The AVERROES trial demonstrated apixaban was superior to aspirin in patients in whom warfarin was unsuitable.⁵⁵ Later, the ARISTOTLE trial demonstrated that apixaban was also superior to warfarin and caused less bleeding.⁵⁶ As with the direct thrombin inhibitors, there is no specific reversal agent for factor Xa inhibitors.

The factor Xa inhibitors have a shorter half-life and they are generally stopped the day prior to a surgery.⁵⁷ As mentioned, there has been little evidence to support any specific strategy of reversal of anticoagulation, and the rare nature of this problem makes randomized trials on the problem difficult to perform. Preliminary evidence suggests that prothrombin complex concentrate (PCC) immediately and completely reverses the anticoagulant effect of rivaroxaban in healthy subjects.⁵⁸ PCC improved laboratory parameters but did not reverse apixaban-induced bleeding in a rabbit model.⁵⁹

DIRECT CURRENT CARIOVERSION

Deep Sedation for Cardioversion

Direct current shocks should never be administered to a conscious patient. A high-energy shock delivered to an awake patient may result in lifelong emotional trauma and has been appropriately termed a calamity.⁶⁰

Our preferred drug for deep sedation before cardioversion is propofol.⁶¹ Dosing must be individualized. A bolus of 0.6 mg/kg usually is effective for routine elective cardioversion but may be excessive in a critically ill patient.⁶² Propofol's adverse effects include apnea, bradycardia, hypotension, nausea, and pain and burning at the intravenous injection site that can be minimized by giving local lidocaine at the site. Overdose is treated with ventilation and oxygen, elevation of the legs, increasing flow rates of intravenous fluids, and administration of pressor agents and anticholinergic agents.

Regardless of who administers sedation, expert ability to manage the patient's airway must be immediately available. Electrophysiology laboratory nurses are often quite capable of administering deep sedation.⁶³ We recommend that an anesthesiologist be present for high-risk patients.

Technical Aspects

When the capacitors of a defibrillator charge, the device becomes capable of energy delivery (measured in watt-seconds or joules [J]). The energy is composed of voltage and current. Transthoracic current flow is partially determined by electrode placement. A variety of configurations has been employed. We have favored an anteroposterior (parasternal and left infrascapular) pathway for cardioverting atrial fibrillation and flutter and other atrial arrhythmias. This configuration provides the best vectors for energy delivery to the atria⁶⁴ (Fig. 31.12). We also have found it to be optimal for patients with an implantable cardioverter-defibrillator (ICD) and epicardial patches.⁶⁵

Most problems with energy delivery have been eliminated with modern external defibrillators that deliver biphasic shocks. Devices with two different biphasic waveforms are available: rectilinear (Zoll Medical, Chelmsford, MA) and truncated exponential (Physiocontrol, Redmond, WA). Head-to-head comparisons have not found significant differences between these biphasic waveforms. Success rates for conversion of atrial fibrillation range from 87% to 100%.

Although it was common to recommend an initial monophasic energy of 100 J for atrial fibrillation (with initial success rates of 50%), we agree with Ewy and begin with 200 J.⁶⁴ An initial monophasic energy of 360 J for atrial fibrillation lasting longer than 48 hours also has been suggested.^{64,66} A similar recommendation of 200 J also applies to biphasic waveforms, particularly for cardioversion in patients with atrial fibrillation of long duration.⁴⁷ Optimal monophasic energy delivery for cardioversion of atrial flutter was 100 J.⁶⁷ We generally use 100 J for biphasic cardioversion of atrial flutter as well.

R-wave synchronization should be ensured during cardioversion of arrhythmias with well-defined QRS complexes. Failure to do so may lead to shock delivery within the “vulnerable period” of the T wave and induction of ventricular fibrillation.

Determinants of Short- and Long-Term Success of Cardioversion

Transthoracic impedance influences current flow and procedural outcome. Current flow is inversely related to impedance. Impedance is influenced by a variety of factors. These factors include the phase of ventilation (impedance is lower with expiration than with inspiration), distance between electrodes, pressure on electrodes (air does not conduct well), effect of previous discharges (decreased impedance), time between discharges (waiting as long as 3 minutes may provide continued decreases in impedance), and patient body habitus (heavier weight or increased body mass index will decrease success).^{64,68}

As noted, modern defibrillators have biphasic waveforms that are more effective per joule output than monophasic waveform defibrillators. Electrode size is also an important determinant of transthoracic impedance. Self-adhesive pads commonly are used in high-risk patients. They are easy to position precisely. Transthoracic impedance may be higher (70 to 100 ohms) with these pads compared with metal electrodes (50 ohms).⁶⁴ Optimal paddle size ranges from 8 to 12 cm. A conductive gel or paste must be used between the metal electrodes and the chest skin.⁶⁴ Smearing gel between paddles may deflect energy away from the heart.⁶⁹ A switch from self-adhesive pads to paddles with pressure is a simple method to increase current delivered per shock and to promote procedural success.

Poor long-term success in cardioversion of atrial fibrillation relates to arrhythmia duration (longer than 1 year) and large left atrial diameter (greater than 5 cm). Untreated hyperthyroidism, mitral stenosis, or CHF increases the likelihood of recurrence. Use of concomitant antiarrhythmic drugs (especially amiodarone) may help maintain sinus

Figure 31.12 Anteroposterior electrode placement for cardioversion of atrial fibrillation and flutter. **A**, Right parasternal anteroposterior electrode placement. **B**, Left parasternal anteroposterior electrode placement. In each instance, the current vector transverses a critical mass of atrial myocardium. The right parasternal position has more of the right atrium between the electrodes and may be advantageous in patients with biatrial disease. The left parasternal position has a smaller interelectrode distance and less lung between electrodes. It has been advocated for patients with left atrial enlargement. (Adapted from Ewy GA: The optimal technique for electrical cardioversion of atrial fibrillation. Clin Cardiol 1994;17:79-84.)

rhythm. Atrial flutter recurrences are hard to prevent, even with pharmacotherapy. As mentioned earlier, typical atrial flutter should be eliminated with radiofrequency catheter ablation.

A BRIEF REVIEW OF ANTIARRHYTHMIC DRUGS

Initiation of chronic oral antiarrhythmic drug therapy for tachyarrhythmias usually is in the realm of practice of general cardiologists and electrophysiologists. Nevertheless, intensivists should be familiar with these agents, as well as current philosophies for their use. The older class IA drugs, including quinidine, procainamide, and disopyramide, now are rarely used because of the risk of QT prolongation and torsades de pointes, low efficacy rates, and poor noncardiac side effect profiles resulting in high discontinuation rates.^{48,70} Antiarrhythmic drugs in common use are described next.

Flecainide (class IC) is an excellent drug for treatment of all supraventricular tachycardias including atrial fibrillation. It is contraindicated in patients with coronary artery disease or significant left ventricular dysfunction (<40%). The typical starting dose is 100 mg given orally twice daily. The maximum recommended dose for paroxysmal supraventricular tachyarrhythmias is 300 mg/day. Potential adverse effects include proarrhythmia (incessant monomorphic ventricular tachycardia), exacerbation of CHF, and “organization” of atrial fibrillation to atrial flutter with a rapid ventricular response (1:1 AV conduction). Ventricular proarrhythmia is unlikely in the absence of significant structural heart disease (incidence approximately 2%). Flecainide has relatively few noncardiac side effects.

Propafenone (class IC) is an equally effective drug for control of supraventricular tachycardia and atrial fibrillation. Newly formulated sustained-release propafenone has more convenient twice-daily dosing, starting at 225 mg orally twice daily, titrated up to 425 mg twice daily if necessary. Sustained-release propafenone was safe and effective in a large outpatient trial (RAFT).⁷¹ Side effects are similar to those of flecainide, with the addition of a “metallic taste in the mouth” (an unusual noncardiac side effect), which does not require drug discontinuation. Propafenone or flecainide can be beneficial on an outpatient basis in patients with paroxysmal atrial fibrillation who are in sinus rhythm when the drug is initiated.⁷² Propafenone has mild β -blocking properties (more prominent in slow metabolizers) but usually not enough to rely on for AV blockade in atrial fibrillation or atrial flutter. Like flecainide, propafenone should not be used in patients with significant structural heart disease.

Sotalol (class III) generally is chosen for patients with coronary artery disease (or other structural heart disease), but can also be a first-line drug for atrial fibrillation in patients with no structural heart disease. It has β -blocking effects and blocks the rapid component of the delayed rectifier potassium current. Sotalol is renally excreted, and doses must be adjusted downward in patients with renal insufficiency. A 3% to 7% risk of torsades de pointes exists with sotalol, with this disturbance usually occurring in the first week of therapy. Other side effects include CHF, exacerbation of bronchospasm, bradycardia, and fatigue. The

starting dose is 80 mg given orally twice daily, titrated up to 160 mg twice daily if necessary and as tolerated. Controversy exists over whether sotalol can be initiated as outpatient therapy. We recommend hospitalization with telemetry monitoring and daily 12-lead ECGs for safe initiation of sotalol.

Dofetilide (a class III agent) blocks the rapid component of the delayed rectifier potassium current. Similar to other class III drugs, it prolongs the QT interval and can cause torsades de pointes. In the United States, physicians must take a course and certify to use dofetilide. The drug is dispensed by a national registry system to ensure the physician writing the prescription is certified. Its main advantage is that it has a low proarrhythmia profile (with proper dosing) when used in patients with low ejection fractions. A second virtue is that it does not precipitate or aggravate CHF. The dosage range is 125 to 500 μ g given twice daily, which is adjusted according to renal function and QT interval prolongation. Inpatient monitoring on a telemetry ward and frequent ECGs (obtained 2 hours after each dose) to monitor the QT interval are requirements for initiation of dofetilide therapy. The drug is, therefore, rather inconvenient to use. However, it is the only alternative to amiodarone for treatment of atrial fibrillation in patients with poor left ventricular function. Dofetilide usually is well tolerated, with few noncardiac side effects.

Amiodarone is a class III antiarrhythmic with sodium, potassium, and calcium channel blocking properties. In addition, it is a noncompetitive beta blocker and inhibits peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). It is considered the best atrial fibrillation rhythm control drug and generally regarded as the most effective antiarrhythmic agent for all tachyarrhythmias.⁴¹ It is an excellent AV node-blocking drug. Even when the drug fails to achieve AF rhythm control, it usually will provide good rate control. Amiodarone has an extremely long half-life (a virtue for compliance, but a liability if side effects occur). Like dofetilide, it can be used in patients with low ejection fraction at risk of heart failure exacerbation. Amiodarone does not adversely affect survival and in some studies offered some protection against arrhythmia-related sudden death.⁶⁵⁻⁶⁷ It can cause significant bradycardia but is associated with a very low incidence of ventricular proarrhythmia (less than 1%), despite the fact that it prolongs the QT interval. The drug requires an initial loading dose (regimens vary). A maintenance dose in the range of 200 mg (or less) per day usually can be achieved and is helpful in minimizing side effects. Occasionally, maintenance doses of 400 mg per day are required for tachycardia control. Amiodarone's long-term noncardiac side effects are significant and should limit its use in younger patients. Nevertheless, amiodarone is the most frequently prescribed specific antiarrhythmic drug in the United States. Side effects include pulmonary toxicity, polyneuropathy, photosensitivity, bradycardia, hepatic dysfunction, thyroid dysfunction, and ophthalmologic complications. Side effects are correlated with maintenance dose and duration of therapy. Baseline pulmonary function studies with diffusing capacity, chest radiograph, liver and thyroid function studies, and eye examination should be performed before or shortly after the drug is started. We recommend thyroid function tests, liver function tests, and a chest radiograph every 6 months

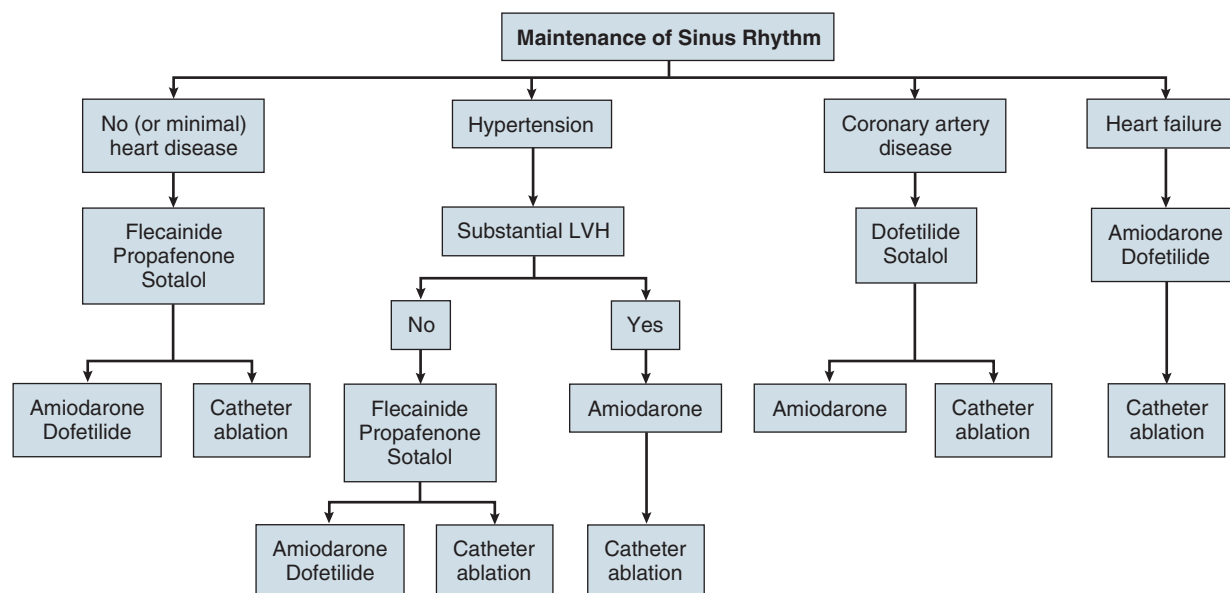

Figure 31.13 ACC/AHA/ESC 2011 guideline algorithm for oral antiarrhythmic drug therapy for maintenance of sinus rhythm in patients with atrial fibrillation. Although the figure suggests that dofetilide is a first-line agent for treatment of coronary artery disease, the text of the guidelines describes it as a second-line agent. LVH, left ventricular hypertrophy. (From Wann LS, Curtis AB, January CT, et al, writing on behalf of the 2006 ACC/AHA/ESC Guidelines for the Management of Patients With Atrial Fibrillation Writing Committee: 2011 ACCF/AHA/HRS focused update on the management of patients with atrial fibrillation (updating the 2006 guideline): A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2011;57:223-242.)

to look for signs of toxicity. It is particularly disturbing that pulmonary toxicity (which may be fatal) may be missed even with careful surveillance.

Dronedarone is a derivative of amiodarone developed for the treatment of atrial fibrillation and atrial flutter. Like amiodarone, dronedarone is a potent blocker of multiple ion currents, including the rapidly activating delayed-rectifier potassium current, the slowly activating delayed-rectifier potassium current, the inward rectifier potassium current, the acetylcholine activated potassium current, peak sodium current, and the L-type calcium current. Dronedarone also exhibits antiadrenergic effects. Dronedarone has been studied for maintenance of sinus rhythm and control of ventricular response during episodes of atrial fibrillation. Dronedarone reduces mortality rate and morbidity in patients with high-risk atrial fibrillation but may be unsafe in patients with persistent or permanent atrial fibrillation as well as individuals with severe heart failure.^{73,74}

The AFFIRM trial randomized over 4000 patients to receive rate or rhythm control treatment strategies (plus warfarin sodium in both treatment groups). Because AFFIRM demonstrated no significant stroke, quality of life, or mortality rate differences with rhythm versus rate control, physicians must consider the risk-benefit ratio of antiarrhythmics to maintain sinus rhythm.⁷⁵⁻⁷⁷ Patients with brief or minimally symptomatic recurrences of paroxysmal atrial fibrillation often do not require antiarrhythmic drugs. Patients with troublesome symptoms generally require suppressive antiarrhythmic therapy. Rate control and prevention of thromboembolism are appropriate in both situations.⁵⁰

The 2011 ACC/AHA/ESC guidelines for the management of patients with atrial fibrillation recommend that antiarrhythmic drugs for rhythm control of paroxysmal

atrial fibrillation be chosen using an algorithm (Fig. 31.13).⁵⁰

This algorithm takes into account whether or not the patient has structural heart disease, hypertension with or without “significant” left ventricular hypertrophy (echo wall thickness of 1.4 cm or greater), or coronary artery disease. If there is no structural heart disease, or minimal left ventricular hypertrophy only, the therapeutic agents of first choice are flecainide, propafenone, and sotalol. Second-line therapeutic options include amiodarone and dofetilide. If significant left ventricular hypertrophy is present, the treatment of first choice is amiodarone therapy. If coronary artery disease is present, the treatment of choice is sotalol (because of its β -blocking properties), with second-line therapies including dofetilide and amiodarone. If clinical heart failure is present, first-line agents are amiodarone and dofetilide.

Catheter ablation is recommended for patients with symptomatic paroxysmal atrial fibrillation refractory to or intolerant of at least one antiarrhythmic medication. Catheter ablation is considered reasonable for symptomatic paroxysmal atrial fibrillation prior to initiation of antiarrhythmic drug therapy or symptomatic persistent atrial fibrillation refractory to or intolerant of at least one antiarrhythmic medication. Catheter ablation may be considered for symptomatic persistent or longstanding persistent atrial fibrillation prior to initiation of antiarrhythmic drug therapy and for longstanding persistent symptomatic atrial fibrillation refractory to or intolerant of at least one antiarrhythmic medication.⁷⁸

VENTRICULAR ARRHYTHMIAS

The intensivist must be prepared to recognize and participate in the management of ventricular arrhythmias.

However, long-term management usually is prescribed by cardiologists and electrophysiologists. Therefore this section concentrates on the intensive care and emergency treatment of ventricular arrhythmias and only briefly addresses chronic therapy. The emergency treatment of cardiac arrest is covered in Chapter 1.

ARRHYTHMOGENESIS

Reentry is the most common mechanism for sustained ventricular arrhythmias. Three conditions are required for reentry. The first is the presence of two anatomically contiguous pathways separated by a central region of inexcitable tissue. Second, there must be unidirectional block in one of the pathways. Third, a zone of slow conduction also must be present to allow recovery and excitation of the region of block. Such conditions may be anatomically defined (as in the border zone of an old myocardial infarction scar) or result from functional disturbances in conduction and refractoriness.

Enhanced automaticity results in spontaneous impulse formation in cells that otherwise do not exhibit pacemaker activity. Diseased cardiac tissue is particularly susceptible to development of enhanced automaticity. This may result in rates faster than the normal pacemaker activity of the sinus node. Automatic cells (in the AV node, the His-Purkinje system, or the ventricles) may usurp the sinus node by means of enhanced automaticity if their depolarization is accelerated by drugs, sympathetic activity, or metabolic disturbances.

Triggered activity occurs when oscillations in membrane potential (called afterdepolarizations) reach the threshold for action potential formation, resulting in abnormal impulse formation. Early afterdepolarizations (EADs) result from delayed inactivation of inward ion currents during the plateau phase of the action potential. EADs appear to be important in the genesis of torsades de pointes (see later). Delayed afterdepolarizations (DADs) result from increased intracellular calcium. Digitalis toxicity is the classic example of DAD-induced triggered activity. Digitalis inhibits the $\text{Na}^+\text{-K}^+$ pump, thereby increasing intracellular Na^+ , which in turn increases intracellular Ca^{2+} via the $\text{Na}^+\text{-Ca}^{2+}$ exchange current.⁷⁹ Idiopathic outflow tract ventricular tachycardia may also result from DADs (cyclic AMP-mediated triggered activity).⁸⁰

METABOLIC DISTURBANCES AND ISCHEMIA

Metabolic disturbances and ischemia are common in the critically ill. Patients may suffer from (synergistic or opposing) effects of multiple abnormalities. In the presence of partial predispositions, arrhythmias may not develop until patients are exposed to factors resulting in enhanced automaticity, delayed conduction, or changes in refractoriness.

Hypokalemia delays repolarization and prolongs action potential duration. This may lead to EADs and triggered arrhythmias. Hypomagnesemia and hypokalemia often coexist. Each is associated with QT prolongation and torsades de pointes. Repletion of Mg^{2+} is an important adjunct to the management of hypokalemia. Hypermagnesemia usually is not associated with arrhythmogenesis.

Hyperkalemia suppresses automaticity and slows conduction. The earliest ECG sign is peaked T waves. At high levels (usually 7.0 mEq/L or greater), marked QRS widening (sine wave morphology) may be seen, followed by cardiac arrest. Patients with renal insufficiency may be particularly susceptible. Cardiac effects of severe hyperkalemia may be lethal and require prompt intervention. The most rapid means of countering cardiac toxicity is intravenous administration of 10% calcium chloride. The ECG should be monitored to ensure that signs of hyperkalemia have been reversed. Calcium chloride, although effective emergently, does not lower serum potassium.

Sodium bicarbonate (usual dose 44 to 88 mEq) reduces serum potassium. Regular insulin (10 units) will result in redistribution of K^+ from the extracellular to the intracellular space but does not lower total body potassium stores. Insulin should be followed by 50 mL of 50% glucose.

Further treatment of hyperkalemia involves removal of potassium from the body. The most common method is administration of the cation-exchange resin sodium polystyrene sulfonate (Kayexalate). The usual dose is 50 g given two or three times daily. The most effective means of reducing body potassium is dialysis. Care must be taken to avoid precipitous reduction, especially in patients taking digitalis glycosides.⁸¹ ECG patterns associated with electrolyte and metabolic disturbances are discussed in more detail later in this chapter.

Myocardial ischemia, from coronary artery disease, hemodynamic deterioration, or hypoxemia, can produce a variety of electrophysiologic effects. Acid-base disturbances and exogenous or endogenous catecholamines also can predispose affected patients to ventricular (often polymorphic) arrhythmias. The role of the sympathetic nervous system in arrhythmogenesis and electrical storm cannot be overemphasized.^{79,82,83} Reentry, enhanced automaticity, and triggered activity may all be provoked.

In the absence of QT prolongation, ischemia is the most common cause of polymorphic ventricular tachycardia. Polymorphic ventricular tachycardia/ventricular fibrillation in the early phase (less than 48 hours) of an acute myocardial infarction does not require additional evaluation or treatment. Late polymorphic ventricular tachycardia/ventricular fibrillation complicating myocardial infarction usually occurs when severe heart failure or cardiogenic shock also has been problematic. The initial prognosis usually is determined by hemodynamic recovery rather than arrhythmias.

Ischemia is also a common cause of polymorphic ventricular tachycardia/ventricular fibrillation in the absence of acute infarction. A reduction in or withdrawal of catecholamines should be tried. Beta blockers should be titrated to tolerance. Intra-aortic balloon counterpulsation and acute revascularization should be considered. Pharmacologic therapy with amiodarone may be useful.

DIFFERENTIAL DIAGNOSIS OF WIDE QRS TACHYCARDIA

Wide complex tachycardia (WCT) may be supraventricular or ventricular in origin. Evaluation of WCT remains a common dilemma for clinicians. Numerous algorithms aid in arriving at the correct diagnosis. Unfortunately they are

difficult to remember and an overreliance on algorithms may prevent clinicians from understanding the underlying arrhythmic mechanisms. Presence of AV dissociation is diagnostic of ventricular tachycardia. In general, supraventricular tachycardia with aberrancy will manifest with a typical bundle branch block pattern, whereas ventricular tachycardia will have more “bizarre” QRS complexes. Preexcited supraventricular tachycardias may be impossible to distinguish from ventricular tachycardia using ECG criteria alone. Algorithms (with good sensitivity and specificity) to help distinguish supraventricular tachycardia from ventricular tachycardia are summarized in [Table 31.3](#).⁸³

APPROACH TO VENTRICULAR ARRHYTHMIAS IN THE CRITICALLY ILL

New ventricular arrhythmias warrant an assessment of electrolytes, oxygenation, and acid-base status. Routine measurement of cardiac enzymes is not mandatory with the onset of each arrhythmia. The QT interval should be checked via 12-lead ECG. The 12-lead ECG also is useful in distinguishing monomorphic from polymorphic ventricular tachycardia. Dislodgement of intravascular catheters may result in mechanically induced arrhythmias. Catheter position may be confirmed by x-ray examination or fluoroscopy.

A comprehensive discussion of advanced cardiovascular life support (ACLS) is beyond the scope of this chapter. Current recommendations for management of adult cardiac arrest are discussed in Chapter 1 of this book and are summarized in recently published ACLS guidelines.⁸⁴

SPECIFIC VENTRICULAR ARRHYTHMIAS

The occurrence of premature ventricular contractions (PVCs) and nonsustained ventricular arrhythmias in the ICU generally has little immediate importance. Reduction or withdrawal of exogenous catecholamines and elimination of metabolic disturbances often will decrease the frequency and severity of nonsustained ventricular tachycardia (NSVT). Acute antiarrhythmic drug therapy is rarely required unless symptoms of hemodynamic compromise occur.

The approach to NSVT that persists after recovery from acute illness depends on the underlying cardiac substrate. Asymptomatic persons without structural disease require no therapy. Patients with reduced left ventricular function (less than or equal to 35%) should be evaluated for ICD therapy.⁸⁵⁻⁸⁷ Amiodarone, which has a neutral effect on mortality rates, may be used to suppress symptomatic NSVT in patients with significant structural heart disease.⁸⁵

Acute management of sustained monomorphic ventricular tachycardia depends primarily on its hemodynamic stability. Unstable tachycardia should be treated promptly with direct current cardioversion. Stable arrhythmias may be treated with intravenous amiodarone or beta blockers. Although lidocaine remains an option, the International Cardiopulmonary Resuscitation (CPR) guidelines no longer recommend lidocaine as a first-line agent. Antitachycardia pacing may be considered in patients with transvenous or epicardial pacing leads. If these modalities are unsuccessful (or arrhythmia acceleration occurs), direct current cardioversion can be used to restore sinus rhythm. Electrical storm

Table 31.3 Electrocardiographic QRS Morphology Criteria Favoring Ventricular Tachycardia Over Supraventricular Tachycardia

Study	Morphology	Criteria Favoring Ventricular Tachycardia
Wellens et al, 1978 ^{87a}	RBBB-like	Monophasic R in V ₁ qR, QS, RS in V ₁ rS, QS, qR in V ₆ R/S <1 in V ₆ (S > R or QS in V ₆) Left axis deviation QRS width >140 ms

Vereckei et al, 2008 ^{87e}		Initial R wave in lead aVR Initial r or q wave >40 ms in lead aVR Notch on descending limb of negative onset, predominantly negative QRS in lead aVR v _i /v _t ≤ 1*

From Neiger JS, Trohman RG: Differential diagnosis of tachycardia with a typical left bundle branch block morphology. *World J Cardiol* 2011;3:127-134.

*Ventricular activation-velocity ratio (v_i and v_t = initial and terminal 40 ms, respectively, of QRS complex).

is defined as ventricular tachycardia or ventricular fibrillation occurring more than twice in 24 hours, usually requiring electrical cardioversion or defibrillation.⁸⁸ Although data are limited, beta blockade in conjunction with amiodarone appears to be the most effective therapy for electrical storm.^{82,88}

Because the arrhythmic substrate usually is fixed (most commonly, coronary artery disease and prior myocardial infarction), recurrence rates may remain high even after elimination of “reversible” causes.^{89,90} Although no definite guidelines exist in the presence of reversible causes, an ICD should be strongly considered in patients with left ventricular dysfunction (if comorbidity is not prohibitive). Electrophysiologic testing may be useful in patients with coronary artery disease but is much less reliable in patients with nonischemic cardiomyopathy.

Bundle branch reentry has been reported to account for up to 6% of the cases of monomorphic ventricular tachycardia.⁹¹ This percentage may rise to 40% to 50% in patients with idiopathic dilated cardiomyopathy.⁹² It has been our clinical experience that this arrhythmia is far less frequent. Nevertheless, bundle branch reentry should be considered in patients with marked left ventricular dysfunction (especially nonischemic), intraventricular conduction defects, and wide QRS tachycardia. It may appear after valve replacement surgery. The tachycardia circuit typically uses the right bundle branch as its antegrade limb and the left bundle branch as its retrograde limb. Tachycardia therefore manifests with classic LBBB morphology. Diagnosis and treatment may be accomplished during a single invasive electrophysiology session. The right bundle branch is easily ablated during sinus rhythm, permitting tachycardia cure without detailed mapping during hemodynamically unstable arrhythmias.^{93,94} Although the postablation prognosis has been said to be favorable for patients with isolated bundle branch reentry, patients with residual inducible or spontaneous ventricular tachycardia should be offered ICD therapy. Patients with significant residual infranodal conduction delay (His-ventricular rates longer than 90 ms) after ablation should be considered for permanent pacing (usually with an ICD). It is appropriate to implant an ICD after ablation in patients with heart failure and ejection fractions less than 35%.

Optimal long-term management of patients with structural heart disease and sustained monomorphic ventricular tachycardia is to implant an ICD.^{95,96} Hemodynamic stability does not predict a better long-term outcome.⁹⁵ Ablation generally is regarded as palliative and is used primarily to reduce shock frequency in patients with recurrent ventricular tachycardias.⁹⁷ However, substrate-based catheter

ablation may reduce the ICD therapies in post-myocardial infarction patients who received ICDs for secondary prevention.⁹⁸

The risk of recurrent polymorphic ventricular tachycardia/ventricular fibrillation is high, and the long-term prognosis is poor. Most patients, particularly those with left ventricular dysfunction, should have an ICD implanted if no contraindications exist. Idiopathic ventricular fibrillation may respond to catheter ablation if a single PVC focus (usually from the Purkinje system or the right ventricular outflow tract) is the consistent trigger.^{99,100} Coronary artery spasm may result in ventricular fibrillation caused by myocardial ischemia. Recognition of this uncommon cause of cardiac arrest is critical. Ideal treatment for patients with coronary spasm and associated ventricular arrhythmias remains controversial. Titration of calcium channel blocker dose to prevent ergonovine-induced spasm eliminated arrhythmia in one small series.¹⁰¹ Despite optimal medical therapy (nitrates and calcium channel blockers), this patient subgroup falls into a high-risk category of vasospastic angina and appears to be at greater risk for sudden death. Concomitant ICD implantation has been advocated to reduce this risk.¹⁰²

LESS COMMON SUBSTRATES

Serious ventricular arrhythmias are uncommon in the absence of significant left ventricular dysfunction. A few specific entities should be readily recognized by the intensivist.

IDIOPATHIC VENTRICULAR TACHYCARDIA

Idiopathic ventricular tachycardias tend to originate in a “line of fire” from the right ventricular outflow tract (90%), left ventricular outflow tract, aortic cusps, and mitral annulus.¹⁰³ They often are facilitated by catecholamine infusion. The most common forms (right ventricular outflow tract tachycardia) have a typical, easily recognizable ECG pattern of LBBB with an inferior frontal lead axis (tall R waves in leads II, III, and aVF). These arrhythmias occur in the absence of apparent structural heart disease. Abnormalities may be detected using magnetic resonance imaging; however they do not definitely correlate with sites of arrhythmogenesis.^{104,105} Very frequent episodes may result in a tachycardia-mediated cardiomyopathy.¹⁰⁶

More than 90% of idiopathic ventricular tachycardias can be cured by catheter ablation (Figs. 31.14 and 31.15).^{106,107} The most reliable method for localizing the site of origin is pace mapping. The 12-lead ECG will exactly match the spontaneous ventricular tachycardia QRS morphology at

Figure 31.14 Nonsustained ventricular tachycardia from aortic cusp. An “idiopathic” ventricular tachycardia arising from the aortic cusp. (From Kakodkar S, Krishnan K, Awad S, et al: Reversible cardiomyopathy in an adolescent with idiopathic aortic cusp ventricular tachycardia. *Pediatr Cardiol* 2010;31(1):147-150.)

Figure 31.15 Mapping of a left ventricular outflow tract (LVOT) tachycardia. Using the EnSite system, a three-dimensional electroanatomic mapping was performed during the electrophysiology study. The nonsustained LVOT tachycardia originated from the noncoronary/right coronary cusp border. This arrhythmia was ablated successfully (ablation points shown as blue spheres). Ao, aorta; LV, left ventricle; RV, right ventricle. (From Kakodkar S, Krishnan K, Awad S, et al: Reversible cardiomyopathy in an adolescent with idiopathic aortic cusp ventricular tachycardia. *Pediatr Cardiol* 2010;31(1):147-150.)

the site of origin of the ventricular tachycardia. If a perfect 12/12-lead ECG pace map match can be obtained, the site is ablated. These tachycardias are adenosine-sensitive and thought to be the result of cyclic AMP-mediated DADs.⁸⁰ These arrhythmias may respond to treatment with adenosine and chronically to beta blockers or calcium channel blockers, which normally are ineffective in other ventricular tachycardias.

Another “idiopathic” left ventricular tachycardia manifests as a relatively narrow right bundle branch block (RBBB), left axis deviation tachycardia. The ECG and rhythm strip should be examined carefully for P waves. If the PP interval is slower and the P waves are dissociated, the diagnosis of ventricular tachycardia, rather than supraventricular tachycardia with aberrancy, is confirmed. This arrhythmia is verapamil-sensitive and can easily be ablated if necessary. The arrhythmia is due to macroentry in the terminal Purkinje fibers in the left distal third of the apical septum (Fig. 31.16). To ablate it, the lower third of the septum is mapped, looking for the sharpest, earliest Purkinje potential during ventricular tachycardia.¹⁰⁸ A second technique (also using Purkinje potentials) is equally effective.¹⁰⁹ This reentrant tachycardia is referred to by several different names, including fascicular ventricular tachycardia, verapamil-sensitive ventricular tachycardia, and Belhassen’s ventricular tachycardia.

In patients with ventricular arrhythmias and obvious significant right ventricular disease, the diagnosis of arrhythmogenic right ventricular dysplasia (ARVD)/cardiomyopathy can be made. The left ventricle generally has milder abnormalities. ARVD typically occurs in young patients

(80% of patients are diagnosed before the age of 40 years) and is an important cause of SCD in this population. It should, however, be emphasized that the overall risk of SCD is low (2% to 2.5% per year).¹¹⁰

Males are predominantly affected. ARVD is transmitted in an autosomal dominant pattern with variable penetrance (abnormal loci have been mapped to chromosomal regions 14q23, 1q42, 14q12, 2q32, 17q21, and 3p23).¹¹⁰ Immunohistochemical analysis of endomyocardial biopsy samples revealing a diffusely reduced plakoglobin signal level appears to be a highly sensitive and specific test for ARVD.¹¹¹

Ventricular arrhythmias in ARVD may be catecholamine dependent and are exacerbated during exercise tolerance testing in 50% of patients. Sotalol and amiodarone seem to be effective in ARVD. Catheter ablation has a palliative, complementary role. Arrhythmia recurrences at new foci may occur after apparent ablative success. Experience with ICDs in ARVD is limited. Patients resuscitated from cardiac arrest or those poorly responsive to (or intolerant of) antiarrhythmic drugs appear to be good candidates.¹¹²

The congenital long QT syndrome is a manifestation of a variety of ion channel mutations that result in prolonged ventricular repolarization. The three main features of congenital long QT syndrome are (1) prolongation of the rate-corrected QT interval (QTc); (2) cardiac arrest secondary to torsades de pointes (Fig. 31.17); and (3) QT prolongation, syncope, or sudden death in family members. Syncope often occurs in association with physical activity, emotional reactions, or acute arousal with auditory stimuli (the specific trigger in a variant of long QT syndrome, LQT2).^{113,114} Beta blockers are the mainstay of treatment in patients with long

Figure 31.16 Verapamil-sensitive ventricular tachycardia in a 12-year-old.

Figure 31.17 **A**, Marked QT prolongation and T wave alternans is a harbinger of electrical instability. **B**, Increasing ventricular ectopy is followed by ventricular fibrillation. (Adapted from Trohman RG, Sahu J: Drug-induced torsades de pointes. *Circulation* 1999;99:E7.)

QT syndrome. Permanent pacing (ideally via an ICD) may be beneficial for patients in whom beta blockade is not effective or in whom excessive bradycardia develops. Limited experience has been reported with left cervicothoracic sympathetic ganglionectomy in patients with drug-refractory long QT syndrome and surgical expertise is available in only a few centers. ICDs are recommended for high-risk patients, including those with recurrent syncope on beta blockers, aborted SCD, a strong family history of sudden death, and the Jervell and Lange-Nielsen syndrome (homozygotes or compound heterozygotes with mutations in *KCNQ1* and *KCNE1*, resulting in abnormal I_{Ks} ion current long QT syndrome and hereditary deafness).¹¹⁵

Although the short-term effects of gene-specific therapy (e.g., mexiletine or flecainide in patients with sodium channel abnormalities, potassium plus spironolactone in potassium channel defects) on the QT interval are encouraging,¹¹⁶ long-term data are lacking regarding their ability to prevent arrhythmias in long QT syndrome. A trial of flecainide for another variant of the syndrome, LQT3, is ongoing.

QT prolongation may be acquired (most commonly caused by drug effects or toxic substances, electrolyte abnormalities, hypothermia, and central nervous system injury). Drug-induced QT prolongation usually is the result of I_{Kr} ion current blockade.³⁵ Intensivists need to be particularly aware of the pharmacologic causes of QT prolongation (Box 31.3). Drug-induced torsades de pointes is managed initially with intravenous magnesium sulfate. Isoproterenol and temporary pacing increase ventricular rates, shorten QT intervals, and help prevent recurrent arrhythmias until the effects of the offending agent diminish.

The Brugada syndrome (first described in 1992) is characterized by RBBB with ST-segment elevation in leads V_1 to V_3 , polymorphic ventricular tachycardia, and ventricular fibrillation.¹¹⁷ Intensivists need to be particularly aware that febrile illnesses may trigger arrhythmic events.¹¹⁸ Brugada syndrome has been linked to mutation in the sodium channel gene *SCN5A*. This mutation decreases sodium channel activity. It is inherited in an autosomal dominant pattern with variable penetrance. Males are more likely to be affected and have an increased risk of sudden death, probably related to a more prominent transient outward potassium current. The ECG abnormality originally was thought to be persistent; however, transient forms (in which the ECG may be normal for periods of time) have been described.¹¹⁹ The electrocardiographic abnormalities may be unmasked by procainamide, flecainide, or ajmaline.

The cellular mechanism responsible for the ST-segment elevation is early repolarization of the ventricular epicardium as a result of rebalancing of currents at the end of phase I of the action potential. The transient outward potassium current (I_{to}) overwhelms inward currents. The action potential “dome” is abolished at some sites but not others. Propagation of the dome to sites where it is absent may result in so-called *phase II reentry*, the mechanism of arrhythmogenesis.¹²⁰ In this instance, diminished sodium channel activity facilitates loss of the action potential dome as a result of a negative shift in the voltage at which phase I begins. Different mutations in *SCN5A* appear to account for LQT3; however, a recent report suggests a genetic (and perhaps

Box 31.3 Drugs* Reported to Cause Prolongation of QT Interval or Torsades de Pointes/Ventricular Tachycardia

Antiarrhythmic Medications

Class IA

Quinidine
Procainamide (metabolized to *N*-acetylprocainamide)
Disopyramide

Class III

Dofetilide

[†]Unavailable or severely limited availability in the United States.

clinical) link between the Brugada syndrome and LQT3.¹²¹ As with long QT syndrome, it appears that genetic heterogeneity exists in the Brugada syndrome.¹²² In Japan and Southeast Asia, the Brugada syndrome may account for 40% to 60% of cases of idiopathic ventricular fibrillation. The ICD is the only effective therapeutic intervention against SCD.

Catecholaminergic polymorphic ventricular tachycardia (CMPVT) typically manifests in childhood as syncope or aborted cardiac arrest. Young boys have the worst prognosis (perhaps they are more sensitive to adrenergic stimulation). Beta blockers are the cornerstone of therapy, and dosing may be titrated according to exercise response. In 40% of patients, arrhythmia control will remain inadequate despite dose optimization during repeat exercise testing. ICDs are the therapeutic option of choice in these patients.¹²³

Short-coupled torsades de pointes (SC-TdP) occurs in patients with structurally normal hearts and unremarkable ECG tracings (normal QT intervals). The coupling interval of the initiating beat is invariably less than 300 ms. It is a rare, potentially fatal disorder whose pathophysiology is unknown. The prognosis is poor, and effective pharmacologic therapy has not been identified. ICDs may be the best option. SC-TdP shares features with idiopathic ventricular tachycardia, and speculation that it may respond to catheter ablation if a single PVC focus (usually from the Purkinje system) is the consistent trigger is not unreasonable.^{124,125}

Short QT syndrome (SQTS) is a heritable primary electrical disease characterized by an abnormally short QT interval (less than 300 ms) and a propensity to atrial fibrillation or SCD, or both. As in the long QT syndrome, more than one relevant genetic mutation has been identified. Shortening of effective refractory periods combined with increased dispersion of repolarization is the likely substrate for reentry and life-threatening tachyarrhythmias. The best form of treatment is still unknown, but prevention of atrial fibrillation has been accomplished with propafenone. Implantation of an ICD is recommended for prevention of SCD.^{126,127}

Patients who experience electrical shock (including lightning strikes) sustain a wide spectrum of injuries with unique pathophysiologic characteristics that require special management. Patients with serious burns admitted to the ICU are trauma patients and should be treated accordingly. Initial prediction of outcome for patients who have experienced electrical shock is difficult, because the full degree of injury often is not apparent. SCD due to ventricular fibrillation is more common with low-voltage alternating current, whereas asystole is more frequent with electric shocks from direct current or high-voltage alternating current. Potentially fatal arrhythmias are more likely to be caused by horizontal current flow (hand to hand); current passing in a vertical fashion (from head to foot) more commonly causes myocardial tissue damage. Lightning strike is unique because it causes cardiac and respiratory arrest, resulting in a 25% to 30% mortality rate.¹²⁸

Aggressive and prolonged CPR in patients who have experienced electrical shock is indicated for several reasons.¹²⁹ First, cardiac arrhythmias and prolonged respiratory arrest may be the only clinical problem, especially in patients struck by lightning. Second, as mentioned, patients who

experience electrical shock commonly are young and have few or no comorbid conditions. These young patients may survive prolonged CPR with no or minor sequelae. It is important to remember that keraunoparalysis leading to autonomic dysfunction may masquerade as irreversible neurologic injury in patients who have been electrocuted. For practical purposes, guidelines for CPR as issued by the American Heart Association⁸⁴ still apply. The algorithm for asystole acknowledges that “atypical clinical features” need to be considered in deciding whether CPR should be continued after initial unsuccessful attempts.

If more than one person has been electrocuted at a scene of injury, standard triage practices need to be modified, especially in those struck by lightning. Most patients who do not experience cardiac or respiratory arrest will survive.¹³⁰ Thus, the usual triage principles should be reversed: First responders should focus initially on patients who appear clinically dead *before* patients who show signs of life are treated.

CARDIAC ARREST AND ELECTRICAL STORM

It is estimated that out of hospital sudden cardiac arrest (SCA) tragically ends over 300,000 lives in the United States^{131,132} and is responsible for 3 million deaths worldwide each year.¹³³ Although the number of age-adjusted cardiovascular deaths has declined during the last 50 years, the proportion that are sudden has remained relatively constant (~50%).^{134,135} SCA claims more lives each year than stroke, lung cancer, breast cancer, and AIDS combined.¹³⁶⁻¹³⁸

SCD is defined as natural death due to cardiac causes, foreshadowed by abrupt loss of consciousness, occurring within 1 hour of an acute change in cardiovascular status.^{133,133} Unfortunately, SCA and SCD are nearly synonymous. Worldwide, survival after SCA is dismal (<1%). In the United States, mortality rate after SCA is about 95%.¹³⁴

Merchant and colleagues¹³⁹ estimated the annual incidence of in-hospital cardiac arrest in the United States. Their calculation of approximately 200,000 annual victims provides pivotal perspective on the magnitude of this problem. Despite the similarity in annual incidence, out-of-hospital SCA is far more familiar to the medical community.¹⁴⁰

Coronary artery disease is the primary cause (80%) of out-of-hospital SCA. Nonischemic cardiomyopathies account for 10% to 15%. The remaining 5% are related to valvular disease, inherited ion channel or receptor defects (long QT syndrome, Brugada syndrome, CMPVT, etc.), congenital heart disease, and other causes. Sadly, over 60% of SCA occurs as an initial clinical event or in patients with clinical disease characteristics suggesting relatively low risk.¹³³ Our risk stratification repertoire remains woefully inadequate for the vast majority of out-of-hospital SCA victims.^{131,140,141}

In contrast, most in-hospital cardiac arrests result from preexisting conditions and are not due to sudden-onset cardiac arrhythmias. Progressive respiratory failure and shock are common precipitants. It has been suggested that this information be used to tailor better in-hospital cardiac arrest protocols.¹⁴²

Ventricular fibrillation is the most frequently documented initial rhythm at the time of resuscitation from out-of-hospital cardiac arrest. In over 75% of cases the underlying cause is a ventricular tachyarrhythmia (ventricular fibrillation or pulseless ventricular tachycardia). Primary bradyarrhythmias (e.g., asystole) and pulseless electrical activity are less common.¹⁴³

Interestingly, over 70% of in-hospital cardiac arrests present with asystole or pulseless electrical activity. Ventricular tachyarrhythmias are a far less common presentation (14%-24%).^{142,144,145}

Out-of-hospital survival is linked directly to time between SCA onset and defibrillation or bystander CPR. Time to restoration of spontaneous circulation is also closely correlated with neurologic recovery. Brain damage begins in 4 to 6 minutes.¹⁴⁶ Studies of outcome as a function of initial rhythm recorded at the scene of out-of-hospital cardiac arrest demonstrate that bradyarrhythmias and asystole have the worst prognosis.^{147,148}

Likewise, survival to hospital discharge is substantially increased when the first documented in-hospital cardiac arrest rhythm is “shockable” (pulseless ventricular tachycardia or ventricular fibrillation).¹⁴² Shocks must take priority over CPR. Delayed defibrillation has been associated with a significantly lower probability of survival to hospital discharge.^{149,150} Asystole often occurs late in an arrest (after energy stores required to generate ventricular fibrillation have been exhausted) and can be a surrogate for prolonged downtime.^{140,148} Data exist suggesting that pulseless electrical activity portends a slightly better outcome compared to asystole.^{140,145}

Children suffering in-hospital cardiac arrest have better survival to hospital discharge compared to adults. This is true (due to increased survival after pulseless electrical activity or asystole) despite a significantly lower prevalence of ventricular tachycardia/ventricular fibrillation as the initial rhythm in children suffering cardiac arrest.¹⁴⁶ For in-hospital cardiac arrest, adult survival rates range from roughly 15% to 21%.^{142,144,145} In children, a survival rate of 27% has been reported.¹⁴² Aggressive, prolonged CPR should be considered in young patients (particularly those with few or no comorbid conditions). Young patients may survive prolonged CPR with no or only minor sequelae.^{128,140}

Electrical storm is defined as ventricular tachycardia or ventricular fibrillation occurring two times or more in a 24-hour period, usually requiring electrical cardioversion or defibrillation.¹⁵¹ Small nonrandomized trials demonstrated amiodarone’s safety and efficacy for recurrent drug-refractory sustained ventricular arrhythmias.^{151,152} Intravenous amiodarone is more effective than lidocaine for out-of-hospital ventricular fibrillation resistant to shocks and epinephrine. More amiodarone-treated patients survive to hospital admission.¹⁵³ Fogel and associates demonstrated 80% 1-year survival rate in patients with recurrent hemodynamically unstable ventricular arrhythmias initially treated with intravenous amiodarone who were receiving oral amiodarone at discharge.¹⁵⁴ Patients with electrical storm following myocardial infarction treated with sympathetic blockade followed by oral amiodarone had significantly better short-term mortality rates compared with conventional antiarrhythmic drugs. Patients who received a combination of oral amiodarone and a beta blocker had the best outcomes.⁸²

Although limited data exist, beta blockade in conjunction with amiodarone appears to be the most effective therapy for electrical storm.⁴¹

Key objectives in post-cardiac arrest care include (1) optimizing cardiopulmonary function and vital organ perfusion; (2) transportation to a hospital or critical-care unit with a comprehensive post-cardiac arrest treatment system of care; (3) identification and intervention for acute coronary syndromes; (4) temperature control to optimize neurologic recovery; and (5) anticipation, treatment, and prevention of multiple organ dysfunction.⁸⁴

The most important manifestations of the post-cardiac arrest syndrome are often neurologic. About 80% of patients remain comatose for longer than 1 hour after resuscitation, and less than 50% of admitted patients have a good neurologic recovery. *Targeted temperature management, or therapeutic hypothermia*, is an intervention intended to limit neurologic injury after resuscitation from cardiac arrest.⁸⁴ An Australian trial and a European multicenter trial suggested improved neurologic recovery and decreased mortality rate at 6 months after arrest.¹⁵⁵⁻¹⁵⁷ A 2008 statement from the International Liaison Committee on Resuscitation (ILCOR) incorporated targeted temperature management into the comprehensive treatment bundle of therapy for the post-cardiac arrest syndrome.¹⁵⁸

Several different methods are available for cooling in therapeutic hypothermia. Many techniques use commercially developed equipment specifically designed for targeted temperature management. The optimal regimen is still a matter of debate.¹⁵⁵

Targeted temperature management has been used almost exclusively in patients with an out-of-hospital cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia. There are no data from studies of sufficient quality to recommend this therapy in an adult who has had a cardiac arrest that is not due to a hemodynamically unstable ventricular tachyarrhythmia. Indications and contraindications for targeted temperature management after cardiac arrest are summarized in [Box 31.4](#).¹⁵⁵

CATHETER ABLATION OF CARDIAC ARRHYTHMIAS

Catheter ablation offers curative therapy for paroxysmal supraventricular tachycardias (including those associated with the Wolff-Parkinson-White syndrome), atrial flutter, automatic atrial tachycardias, idiopathic ventricular arrhythmias, bundle branch reentrant ventricular tachycardias, and interfascicular ventricular tachycardias. Success rates in excess of 90% are common among experienced operators.

Catheter ablation is less successful in other (myocardial) ventricular tachycardias associated with structural heart disease and operator success rates are more likely to vary according to expertise and experience. It remains common to restrict these ablations to patients who fail combination therapy with an ICD and antiarrhythmic drugs (usually amiodarone).

As previously noted, catheter ablation may be considered as first-line *treatment* for some patients with atrial fibrillation. The 2012 HRS/EHRA/ECAS Expert Consensus Statement on Catheter and Surgical Ablation of Atrial Fibrillation

Box 31.4 Indications and Contraindications for Targeted Temperature Management in Comatose Patients after Cardiac Arrest

Patients for whom therapeutic hypothermia should be considered

- Adult patients successfully resuscitated from a witnessed out-of-hospital cardiac arrest of presumed cardiac cause (patients after in-hospital cardiac arrest may also benefit)
- Patients who are comatose (i.e., patients with a score on the Glasgow Coma Scale of less than 8 and patients who do not obey any verbal command at any time after restoration of spontaneous circulation and before initiation of cooling)
- Patients with an initial rhythm of ventricular fibrillation or nonperfusing ventricular tachycardia (patients presenting with other initial rhythms such as asystole or pulseless electrical activity may also benefit)
- Patients whose condition is hemodynamically stable (retrospective data suggest that patients in cardiogenic shock may also safely undergo hypothermia treatment)

Patients for whom therapeutic hypothermia should not be considered

- Patients with tympanic membrane temperature below 30° C on admission
- Patients who were comatose before the cardiac arrest
- Pregnant patients
- Patients who are terminally ill or for whom intensive care does not seem to be appropriate
- Patients with inherited blood coagulation disorders

Adapted from Holzer, M: Targeted temperature management for comatose survivors of cardiac arrest. *N Engl J Med* 2010;363:1256-1264.

suggests that first-line ablation is reasonable for paroxysmal atrial fibrillation and may be considered for persistent or even longstanding persistent atrial fibrillation.⁷⁸

Ablation should not be considered curative for atrial fibrillation, although some patients may be arrhythmia free without antiarrhythmic drugs for 5 or more years. Multiple procedures result in higher success rates than a single ablation session. Catheter ablation may also result in pharmacologic arrhythmia control that was not possible before ablation.

A variety of ablation techniques have been employed, although most operators focus primarily on electrically isolating the pulmonary veins (the most common source of triggering atrial ectopy). Linear left atrial lesions may be employed; however, gaps in these lines may create the substrate for reentrant atrial flutter. This limitation has reduced the popularity of linear lesions that were once favored as a routine portion of the procedure.

Other operators have targeted complex fractionated electrograms recorded during atrial fibrillation. The theory behind this technique is that “rotors” or wavelets of reentry (the substrate for atrial fibrillation) can be eliminated. One report has suggested that attacking complex fractionated electrograms adds little to pulmonary vein isolation for

persistent atrial fibrillation.¹⁵⁹ A recent report that utilizes a special computer program to choose target sites has rekindled interest in this technique.¹⁶⁰

Atrial fibrillation ablation success is highly dependent on careful patient selection. Patients with persistent or permanent atrial fibrillation, very large left atria, or age 75 years or older (similar success rates, complications more likely) are less likely to have an optimal outcome. Ideal candidates for catheter ablation of atrial fibrillation have symptomatic episodes of paroxysmal or persistent atrial fibrillation, have not responded to antiarrhythmic drugs, do not have severe comorbid conditions or significant structural heart disease, are younger than 65 to 70 years, have a left atrial diameter less than 50 to 55 mm, and have had persistent atrial fibrillation for less than 5 years.¹⁶¹

Although atrial fibrillation ablation is generally considered safe and effective, devastating complications may occur. The incidence of death associated with atrial fibrillation ablation is 0.1%. This is similar to the risk of death associated with ablation of regular supraventricular tachycardias. Cardiac tamponade is the most frequent fatal complication. Delayed development of an atrioesophageal fistula (10-16 days after procedure) is the second most frequent cause of death.¹⁶² This complication is unique to ablation in the posterior left atrium.

PACEMAKERS AND IMPLANTABLE DEFIBRILLATORS

As a result of an aging population and expanded implantation indications, intensivists are increasingly likely to encounter patients with pacemakers or implantable defibrillators. Patients with these devices may be hospitalized for cardiac or noncardiac ailments.

The classic indication for permanent pacing is symptomatic bradycardia that is not due to a transient cause and is, therefore, unlikely to reverse. Most commonly, this occurs because of SND or AV blockade. Permanent pacing at rates greater than 70 beats per minute and rate-smoothing algorithms are useful to prevent drug-induced torsades de pointes. Pacing at 80 beats per minute may help prevent torsades de pointes and torsades de pointes “storm” in patients with congenital long QT syndrome.^{4,163}

Magnet application to pacemakers may terminate slow reentrant atrial and ventricular tachycardias by creating a competitive, asynchronous paced rhythm that interrupts the reentrant circuit. If this maneuver is used, a defibrillator should be present in case underdrive pacing accelerates the arrhythmia.

Magnet application may also be useful for pacemaker identification and temporary inhibition of ICD tachyarrhythmia therapies. Three pacemaker companies make more than 90% of the pacemakers used in the United States. The device manufacturers have no standardized programmers, so the device brand must be known in order to bring the company-specific programmer to the patient. Medtronic pacemakers usually respond to magnet application by pacing at 85 beats per minute; Boston Scientific (formerly Guidant) devices at 100 beats per minute; and St. Jude devices at 98.6 beats per minute. Pacemakers will return to the programmed lower rate limit when the magnet

is removed. Clinicians also can find out if a patient has a Medtronic pacemaker or implantable defibrillator by calling 1-800-MEDTRONIC; a Boston Scientific or Guidant device by calling 1-800-CARDIAC; and a St. Jude device by calling 1-800-PACEICD. Access to technical experts is also available via these telephone numbers.

The ICD has emerged as accepted therapy for primary and secondary prevention of sudden death.¹⁶⁴ Evidence-based results have demonstrated the clinical benefits of ICD therapy and indications for implantation have expanded rapidly over the past 10 years (Box 31.5).^{165,166} Over 100,000 ICDs are implanted in the United States annually.¹⁶⁷

Nevertheless, ICD therapy has associated risks including infection, inappropriate shocks, proarrhythmic potential, device malfunction, highly publicized manufacturer advisories, and procedural complications, which may adversely affect morbidity and quality of life.¹⁶⁶ Defibrillator implantation is not always psychologically benign. ICD specific adjustment disorders are not uncommon. Syndromes described include anxiety with secondary panic reaction; defibrillator dependence, abuse, or withdrawal; negative body image; and imaginary (phantom) shocks.¹⁶⁸ Recent problems with the Medtronic Sprint Fidelis and the St. Jude Riata and Riata ST transvenous high-voltage leads serve to emphasize the limitations of ICD therapy.^{169,170}

Box 31.5 Implantable Cardioverter-Defibrillator (ICD) Indications

Class I

ICD therapy is indicated in patients:

- Who are survivors of cardiac arrest due to ventricular fibrillation or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes
- With structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable
- With syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or ventricular fibrillation induced at electrophysiologic study
- With LVEF less than or equal to 35% due to prior myocardial infarction who are at least 40 days past myocardial infarction and who are in NYHA functional class II or III
- With nonischemic dilated cardiomyopathy who have an LVEF less than or equal to 35% and who are in NYHA functional class II or III
- With LV dysfunction due to prior myocardial infarction who are at least 40 days past myocardial infarction, have an LVEF less than or equal to 30%, and are in NYHA functional class I
- With nonsustained VT due to prior myocardial infarction, LVEF less than or equal to 40%, and inducible ventricular fibrillation or sustained VT at electrophysiologic study

Class IIa Indications

ICD implantation is reasonable:

- For patients with unexplained syncope, significant LV dysfunction, and nonischemic dilated cardiomyopathy

LV, left ventricle; LVEF, left ventricular ejection fraction; NYHA, New York Heart Association; VT, ventricular tachycardia.

Our increasing risk stratification repertoire remains inadequate for the vast majority of SCA victims.¹⁴¹ Some evidence suggests that only 35% to 51% of patients who are guideline eligible for an ICD receive one.^{171,172} In contrast, a recent analysis of ICD recipients in the National Cardiovascular Data Registry—Implantable Cardiac Defibrillators Registry suggested that 22.5% did not meet evidence-based implantation criteria.¹⁷³ Patients are often referred for ICD replacement with little or no evidence of a well-informed discussion of the risks, expected benefits, and long-term goals of care.¹⁶⁶

Investigators have raised important issues and asked pivotal questions such as the following: Who are we missing? Who are we overtreating? Who is best served by ICD therapy? Should all initial recipients receive replacement ICDs?^{167,174}

Cardiac resynchronization therapy (CRT), or biventricular pacing, is an important therapeutic option with drug-refractory NYHA (New York Heart Association) class III or IV CHF, left ventricular ejection fraction at 35% or less, and a major left-sided conduction delay (QRS duration greater than 120 ms). Patients with RBBB and IVCD derive less benefit from CRT compared with those with a native LBBB. The underlying rhythm should be sinus or atrial fibrillation, with a slow enough ventricular response to allow continuous biventricular stimulation and capture. Biventricular pacing most frequently is used as part of an ICD system (CRT-D). Acute and chronic CHF contributes to the need for tachyarrhythmia treatment in ICD recipients. Although small trials (93 patients in total) have shown that biventricular pacing diminished ventricular arrhythmias, these results were not confirmed in larger trials.⁴

ELECTROCARDIOGRAPHIC PATTERNS INTENSIVISTS SHOULD RECOGNIZE

Intensivists encounter a variety of clinical conditions that have distinct manifestations on the surface ECG. Many of these patterns may be associated with significant brady- or tachyarrhythmias. Recognition of arrhythmic precipitants may be lifesaving in critically ill patients. In this section, we review important surface ECG patterns that are, or may be, associated with significant rhythm disturbances. Every intensivist should be able to recognize them.

ELECTROLYTE, ENDOCRINE, AND METABOLIC ABNORMALITIES

Electrolyte and metabolic abnormalities may affect cardiac depolarization or repolarization. The ECG may be the first clue that an electrolyte or metabolic abnormality is present.

Hyperkalemia is frequent in the critically ill, in particular in patients with impaired renal function. As the serum potassium increases, the ECG follows a characteristic stepwise pattern of derangement. The first sign of hyperkalemia on ECG is peaked T waves. Although there is no universal definition of “peaked,” we agree with the definition of T waves greater than 10 mm in the precordium and 6 mm in the limb leads.¹⁷⁵ In addition to being peaked, the T waves typically appear narrow. At a potassium level of greater than 6.0 mmol/L, T-wave peaking is pronounced, the P wave will begin to lose amplitude, and the QRS complex begins to

widen. At potassium levels greater than 7 mmol/L the P wave is no longer visible and QRS widening progresses. The ensuing ECG pattern is known as sinoventricular rhythm (Fig. 31.18).¹⁷⁶ Sine waves may become present as the widened QRS complex blends into the T wave (Fig. 31.19).¹⁷⁷ An abnormal ECG may be the initial sign of dangerous hyperkalemia and therapy should begin immediately to eliminate the hyperkalemia and stabilize the heart (calcium gluconate infusion).

Hypokalemia also results in characteristic ECG changes. The hallmark of hypokalemia is the U wave, an additional wave seen after the T wave (Fig. 31.20). As the hypokalemia becomes more severe, the U wave increases in amplitude, and T-wave amplitude will decrease. Eventually, the T wave and the U wave may fuse, giving the appearance of a widened T wave. This creates a prolonged QT interval, which may result in torsades de pointes. The risk of hypokalemia-induced arrhythmia is increased in patients receiving digitalis and during myocardial ischemia.¹⁷⁸

Hypomagnesemia is usually associated with potassium depletion. ECG abnormalities seen are produced by hypokalemia. Hypermagnesemia is uncommon and usually associated with renal failure. Observed ECG changes result from

concomitant electrolyte disturbances (hyperkalemia and hypocalcemia).¹⁷⁸

The principal electrocardiographic feature of hypercalcemia is a shortening of the QT interval (Fig. 31.21).¹⁷⁶ This finding is not associated with arrhythmias. In contrast, patients with the rare SQTS have a QTc interval less than 360 ms (typically <300 ms) and a high risk of sudden death due to ventricular fibrillation (Fig. 31.22).¹⁷⁹ Patients often have permanent or paroxysmal atrial fibrillation and occasionally manifest depression of the PR interval. Tall, peaked T waves without flat ST segments and impaired rate-dependent QT shortening has been recorded.¹⁸⁰ SQTS appears to be inherited in an autosomal dominant pattern.

The principal finding in hypocalcemia is a prolongation of the QT interval. It should be noted that, unlike in hypokalemia, the T wave is normal sized and QT interval prolongation results from lengthening of the ST segment, not a broadening of the T wave due to fusion with a U wave. In severe hypocalcemia, PR and QRS intervals are frequently prolonged (Fig. 31.23).¹⁷⁶ Second-degree or third-degree AV block has been reported. J waves (see later) have occasionally been reported.¹⁷⁸

Figure 31.18 Sinoventricular rhythm. In severe hypokalemia, P waves are no longer visible. QRS widening also occurs. This rhythm is difficult to distinguish from an accelerated idioventricular rhythm. (From Baltazar RF: Basic and Bedside Electrocardiography. Philadelphia, Lippincott Williams & Wilkins, 2009.)

Figure 31.19 Sine waves seen in severe hyperkalemia. (From NEJM Image Challenge, <http://www.nejm.org/action/showImageChallenge?ci=05032012>, last accessed 6/13/12.)

Figure 31.20 Hypokalemia. Prominent U waves are seen here (arrow).

Figure 31.21 Hypercalcemia. A short QT segment is noted. This patient had a calcium level of 16 mg/dL. (From Baltazar RF: Basic and Bedside Electrocardiography. Philadelphia, Lippincott Williams & Wilkins, 2009.)

Figure 31.22 Patient with congenital short QT syndrome. (From http://www.shortqtsyndrome.org/dr_diagnosis.htm, last accessed 6/13/12.)

In addition to electrolyte abnormalities, metabolic derangements can cause characteristic ECG findings. Hypothermia, both from accidental exposure as well as therapeutic cooling after cardiac arrest, has classic findings on ECG (Fig. 31.24).¹⁸¹ As the core body temperature drops below 32° C, conduction becomes slower with slower sinus rates, prolonged PR and QT intervals, as well as junctional rhythms.¹⁸² The finding of an Osborn or J wave is a hallmark of hypothermia. This wave appears as an upward deflection at the terminal portion of the R wave, before the J point. Additionally, the ECG baseline may have artifact or oscillations from shivering. Though classically associated with hypothermia, the Osborn wave may also be a sign of other conditions such as sepsis and diabetic ketoacidosis (which can be hypothermic conditions) as well as normothermic conditions such as neurologic insults and hypercalcemia.¹⁸³

Hypothyroidism characteristically shows slowing of conduction and often has sinus bradycardia, low voltage, and prolonged PR and QT intervals as well as intraventricular

Figure 31.23 Hypocalcemia. A prolonged QT interval is the principal finding in hypocalcemia. Serum calcium is 7.2 mg/dL. (From Baltazar RF: Basic and Bedside Electrocardiography. Philadelphia, Lippincott Williams & Wilkins, 2009.)

conduction delays. Hyperthyroidism may cause sinus tachycardia and premature atrial complexes or may precipitate atrial fibrillation.

BRUGADA PATTERN

As mentioned earlier, the Brugada syndrome is characterized by an inherited disorder of sodium channels. Brugada pattern is characterized on the ECG by RBBB (complete or incomplete) morphology and abnormal repolarization characterized by ST-segment elevation in leads V₁ to V₃. Three distinct patterns have been identified. Type 1 features a “coved” type ST segment (more than 2 mm) elevation and a negative T wave. Type 2 features a “saddleback” ST-T configuration, recognized by two notches in the T wave. Type 3 can have a coved or saddleback morphology. This configuration is less specific for Brugada syndrome (Fig. 31.25).¹⁸⁴ A patient with any of the Brugada patterns and a history of cardiac arrest, syncope, or ventricular tachycardia should have an ICD implanted, as there is no effective drug therapy for this disease. It is not recommended that asymptomatic patients with the Brugada pattern on ECG receive a defibrillator, and clinical monitoring is advised instead. Should a patient suffer from electrical storm, isoproterenol is considered useful.¹³²

Figure 31.24 Osborn waves in hypothermia. Core body temperature of 27.1°C. Triple arrows show shivering artifact. The single arrows show Osborn waves (an upward deflection at the terminal portion of the R wave, before the J point). (From Sepehrdad R, Paulsen J, Amsterdam EA: The ECG that came in from the cold. *Am J Med* 2012;125(3):246-248.)

Figure 31.25 Brugada patterns type 1, 2, and 3. See text for details. (From Koonlawee Nademanee, Silvia G, Priori SG, et al: Proposed diagnostic criteria for the Brugada syndrome: Consensus report. *Circulation* 2002;106:2514-2519.)

LONG QT SYNDROMES

As mentioned previously, the congenital long QT syndrome is associated with SCD due to torsades de pointes. The three most common inherited forms (LQT1, LQT2, and LQT3) represent 75% of the inherited long QT syndrome. Each one of those subtypes has a specific mutation and an activity in which the arrhythmia (and hence syncope or cardiac arrest) is triggered. LQT1 is associated with events during exertion, LQT2 is associated with events occurring after hearing a sudden loud noise, and LQT3 is associated with events at rest or sleep. There are also ECG patterns associated with each of those three variants, though it should be noted that the clinical scenario will often correlate better than the ECG pattern to the specific gene mutation. The LQT1 has a broad T wave, the LQT2 has a bifid T wave, and the LQT3 has a long isoelectric segment and a narrow T wave. The LQT3 pattern appears somewhat similar to the ECG seen in hypocalcemia (Fig. 31.26).¹⁸⁵

More commonly, however, intensivists will see patients with transient prolongations in their QT interval due to their illness, ingestion of medications, or antiarrhythmic drugs. These patients need to be monitored carefully for the development of torsades de pointes. In addition, an alternation in T wave amplitude can be seen. This is referred to as T wave alternans and represents a harbinger of worsening arrhythmias (Fig. 31.27). Dramatic QT

Figure 31.26 Long QT patterns based on genetic mutation. See text for details. (From Roden DM: Long-QT syndrome. *N Engl J Med* 2008;358:169-176.)

prolongation and T wave stroke may occur after cardiovascular accident.

TORSADES DE POINTES

The term *torsades* or *torsades de pointes* refers to a polymorphic ventricular tachycardia that appears to rotate around a horizontal axis, hence the name (from the French “twisting of the points”) (Figs. 31.28 and 31.29).³⁴ The term *torsades de pointes* should be used only in the setting of the ventricular tachycardia seen with a prolonged QT interval (either acquired or congenital). It is important to differentiate this rhythm from other types of polymorphic ventricular tachycardia (as seen in ischemia) because the management is different. Urgent management of acquired long QT prolongation and *torsades de pointes* is typically intravenous magnesium sulfate and defibrillation for hemodynamic instability. As mentioned previously, isoproterenol and temporary pacing increase ventricular rates, shorten QT intervals, and help prevent recurrent arrhythmias until the effects of the offending agent diminish. *Torsades de pointes* is often initiated by a short-long-short sequence of a premature ventricular beat (short segment) followed by a compensatory pause (long segment). The long delay from the compensatory pause delays repolarization. As a result, the QT segment is prolonged after the compensatory pause, and it is more likely that the next depolarization will occur when the ventricle is vulnerable (R on T phenomenon).

Figure 31.27 T wave alternans. Dramatic QT prolongation and T wave alternans after cardiovascular accident. T wave stroke is considered a harbinger of arrhythmias. A short run of *torsades de pointes* was subsequently noted.

Figure 31.29 *Torsades de pointes*. An episode of *torsades* following a short-long-short sequence. (Adapted from Gupta A, Lawrence AT, Krishnan K, et al: Current concepts in the mechanisms and management of drug-induced QT prolongation and *torsades de pointes*. Am Heart J 2007;153(6):891-899.)

WOLFF-PARKINSON-WHITE PATTERN

As described previously, patients with Wolff-Parkinson-White syndrome can present in sinus rhythm or during an arrhythmia. There are three classic ECG patterns in this disorder depending on the patient's presenting rhythm. Patients in sinus rhythm with activation of the ventricle by both the normal AV node and His-Purkinje system as well as by the accessory pathway will have a fusion beat on their ECG. This beat manifests as a delta wave and short PR interval as part of the ventricle is activated (preexcited) by the accessory pathway (Fig. 31.30). Patients with Wolff-Parkinson-White pattern in sinus rhythm are asymptomatic and usually come to attention when presenting for other reasons, after an arrhythmia has broken, or on a routine ECG that incidentally detects the abnormality. T-wave inversion may develop after accessory pathway ablation (Fig. 31.31). This is a transient, reversible, repolarization phenomenon and does not reflect myocardial ischemia.

Patients with an accessory pathway often present for the first time when they have palpitations. More often, the patients will present with an AVRT. In orthodromic AVRT, the conduction travels down the normal conduction system and retrograde up the accessory pathway. The QRS will be narrow (unless there is a preexisting or rate-related bundle branch block) and the delta wave will no longer be visible (the ventricle is entirely activated by the normal conduction pathway). In antidromic AVRT, the conduction will proceed antegrade down the accessory pathway and retrograde up the normal conduction system. There will be a wide complex regular tachycardia (maximal preexcitation).

Atrial fibrillation in a patient with Wolff-Parkinson-White must be recognized as it requires specific treatment, which

Figure 31.28 *Torsades de pointes*. The ventricular tachycardia on electrocardiogram appears to rotate around a horizontal axis, hence the name *torsades de pointes*, from the French “twisting of the points.” (Adapted from Gupta A, Lawrence AT, Krishnan K, et al: Current concepts in the mechanisms and management of drug-induced QT prolongation and *torsades de pointes*. Am Heart J 2007;153(6):891-899.)

Figure 31.30 Wolff-Parkinson-White (WPW) pattern in sinus rhythm. In sinus rhythm, patients with a WPW pattern will have a delta wave, which is a fusion of normal conduction and conduction down the accessory pathway. The PR interval will be short as the accessory pathway will allow part of the ventricle to be activated earlier than the rest of the ventricle is activated by normal pathway.

is different from other forms of atrial fibrillation. The ECG shows an irregular rhythm with a delta wave. The ventricle is again being depolarized from both normal pathway as well as the accessory pathway. As mentioned earlier, AV nodal blocking agents, which are the mainstay of treatment in most cases of atrial fibrillation, may facilitate conduction down the accessory pathway. Decremental conduction (like the AV node) is rare in these accessory pathways and atrial fibrillation may be conducted very rapidly to the ventricles. There is a concern for triggering ventricular tachycardia or fibrillation, so drug therapies include ibutilide (which blocks the accessory pathway) or amiodarone (which blocks both the AV node and the accessory pathway). Additionally, both of these medications can convert atrial fibrillation back to sinus rhythm.

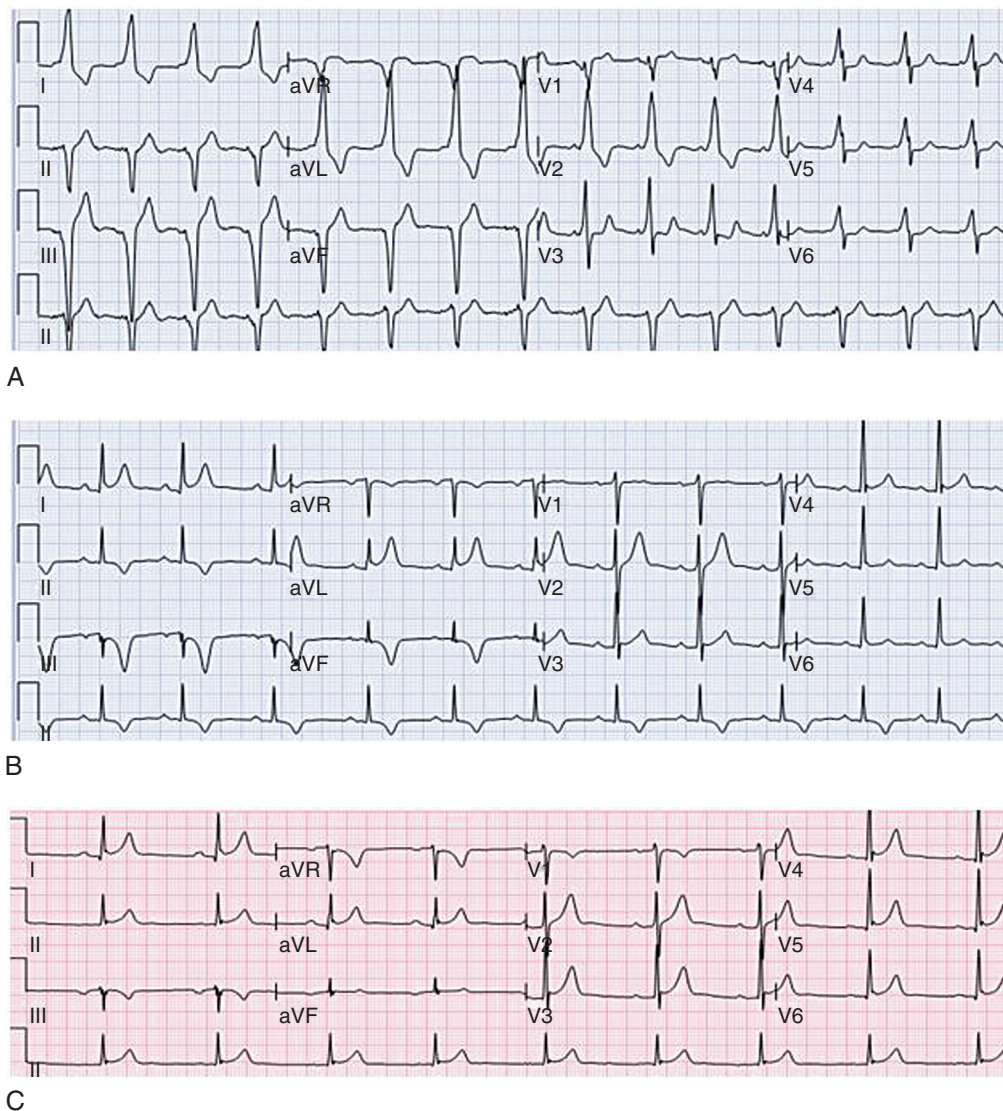

Figure 31.31 **A**, Memory T waves after ablation in Wolff-Parkinson-White (WPW) syndrome. Before procedure, note the delta wave. **B**, Memory T waves after ablation in WPW. After procedure, note the deep T-wave inversions. This is termed T-wave memory. **C**, Memory T waves after ablation in WPW syndrome. Normalization 1 week after ablation. Patients with WPW syndrome have an abnormal depolarization pattern, as evidenced by the delta wave. They also have repolarization abnormalities. Some of those repolarization abnormalities may become manifest after ablation of the accessory pathway. Here a patient with WPW syndrome had deep inverted T waves in the inferior leads after ablation of his accessory pathway. This pattern resolved 1 week later.

Figure 31.32 Arrhythmogenic right ventricular dysplasia (ARVD) with epsilon wave. Electrocardiogram in patient with ARVD. Note the T-wave inversion in V_3 and the incomplete right bundle branch block pattern. The upward deflection after the QRS in V_1 is termed an epsilon wave and is classic for ARVD.

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA

In patients with ARVD, inverted T waves may be noted in the right precordial leads (V_1 , V_2 , and V_3). In addition, an upward deflection, called an epsilon, may be seen just after the QRS complex and is due to late right ventricular activation (Fig 31.32).¹⁸⁶ In addition, the QRS duration will be prolonged, often with a complete or incomplete RBBB pattern. The ECG may be the initial clue to this disease. Ventricular tachycardia with a LBBB-like morphology (right ventricular origin) is often precipitated by catecholamines (e.g., exercise).

CONCLUSIONS

The intensivist must have a keen awareness of patterns, mechanisms, precipitants, and treatment of cardiac arrhythmias. The intensivist must remember that *all* antiarrhythmic therapies (pharmacologic and nonpharmacologic) have the potential for adverse effects. Reducing and eliminating arrhythmia precipitants may be safer and more effective than dramatic interventions. Antiarrhythmic drugs should be chosen carefully and the patient monitored closely. Direct current cardioversion should be used aggressively when the situation is emergent, cautiously when elective, and eschewed when futile. Ablation is effective therapy for most supraventricular tachycardias, idiopathic ventricular

tachycardia, and bundle branch reentry and may be used as adjuvant therapy for patients with frequent appropriate ICD shocks. ICDs are the therapy of choice for primary and secondary prevention of SCD in patients with structural heart disease. Consultation with a cardiac electrophysiologist should be considered a routine part of the critical care physician's armamentarium.

KEY POINTS

- Intensivists managing arrhythmias must have expertise in electrocardiography, pharmacokinetics, pharmacodynamics, and bedside clinical acumen.
- All antiarrhythmic therapies (pharmacologic and nonpharmacologic) have the potential for adverse effects.
- Patients in an intensive care setting frequently have active arrhythmia precipitants. They include hypoxemia, excess circulating catecholamines, CHF, fever (sepsis), pulmonary emboli, electrolyte, and other metabolic disturbances. Reducing or eliminating arrhythmia precipitants may be safer and more effective than dramatic antiarrhythmic interventions.
- Direct current cardioversion of tachyarrhythmias should be used aggressively when emergent (angina pectoris, CHF, hypotension), cautiously when elective, and eschewed when futile. The critical care physician must carefully weigh the risks and benefits of direct current cardioversion for each patient.
- Left ventricular dysfunction is the most important predictor of cardiac death in patients with ventricular arrhythmias. Long-term management of sustained ventricular arrhythmias in the setting of structural heart disease is usually best accomplished with an ICD.
- Diagnosis and management of complex arrhythmias may be facilitated by consultation with a cardiac electrophysiologist.
- Ablation of cardiac arrhythmias often is first-line elective therapy for most supraventricular tachycardias and some ventricular tachycardias.
- Electrocardiographic data stored in permanent pacemakers and ICDs can easily be assessed to help the intensivist determine the patient's recent history and the frequency, rate, and duration of arrhythmias.
- Antiarrhythmic drugs can raise pacing and defibrillator thresholds and change supraventricular tachycardia and supraventricular tachycardia rates, necessitating device reprogramming.
- Intensivists encounter a variety of clinical conditions, which have distinct manifestations on the surface ECG. Recognition of arrhythmic precipitants may be lifesaving in critically ill patients.

The profile of valvular heart disease in the critical care setting has evolved substantially over the past several decades. Aortic stenosis, mitral insufficiency, and aortic insufficiency are the most common valve diseases seen in the intensive care unit, but hypertrophic obstructive cardiomyopathy and mitral stenosis remain important entities as well. Patients with valvular heart disease in critical care units typically fall into one of two categories: (1) those who are critically ill because of valvular dysfunction or (2) those in whom valvular disease represents an important comorbid condition. Many patients present without prior diagnosis of heart valve disease, either because the progression has been insidious and the disease not previously diagnosed or because the onset has been acute. Improvements in technology and the ubiquitous availability of echocardiography have improved diagnosis, while clinician skills at integrating physical examination and other data have generally atrophied during this same time frame.

Rheumatic heart disease accounted for 50% or more of admissions for heart disease in the first half of the twentieth century, with congenital heart disease representing the other major indication for valve surgery through the 1960s.¹ With evolving technology and an increase in average life expectancy, heart valve surgery has shifted to valve repair, as well as replacement for a variety of acquired valvulopathies.

The therapeutic armamentarium, once limited to minimal supportive medical therapy, then solely to valve replacement, has expanded to a variety of surgical repair techniques; a multitude of tissue and mechanical valve options for replacement; and, most recently, an expanding set of percutaneous interventions including percutaneous valve implantation and repair. In addition, various mechanical devices for temporary hemodynamic support are important adjuncts to the management of patients with valvular heart disease in the critical care setting.

Diagnosis of valvular heart disease in critical care units is challenging, with lack of a quiet environment for auscultation; comorbid conditions that affect physical findings; and stress, infection, or metabolic abnormalities that result in tachycardia and shorter intervals for evaluation of heart sounds. Patients in a low output state have softer heart sounds and murmurs as well. In addition, clinical reliance on physical examination has fallen, as has the ability to make accurate diagnosis of valve disease.² A delay in recognizing the presence of significant valve dysfunction continues to occur frequently, and some patients who have had prior routine medical outpatient care nevertheless present with undiagnosed valvular heart disease.³ The currently accepted thresholds for mild, moderate, and severe valvular heart disease are shown in [Table 32.1](#).

Table 32.1 Classification of Severity of Valvular Heart Disease Based on ACC/AHA Guidelines**A. Left-sided Valve Disease**

Indicator	Mild	Moderate	Severe
Aortic Stenosis			
Jet velocity (m/sec)	<3.0	3-4	>4
Mean gradient (mm Hg)*	<25	25-40	>40
Valve area (cm ²)	>1.5	1-1.5	<1
Valve area index (cm ² /m ²)			<0.6
Mitral Stenosis			
Mean gradient (mm Hg)*	<5	5-10	>10
Pulmonary artery systolic pressure (mm Hg)	<30	30-50	>50
Valve area (cm ²)	>1.5	1-1.5	<1.0
Aortic Regurgitation			
<i>Qualitative</i>			
Angiographic grade	1+	2+	3-4+
Color Doppler jet width	Central jet, width <25% of LVOT	Greater than mild but no signs of severe AR	Central jet, width >65% LVOT
Doppler vena contracta width (cm)	<0.3	0.3-0.6	>0.6
<i>Quantitative (cath or echo)</i>			
Regurgitant volume (mL/beat)	<30	30-59	>60
Regurgitant fraction (%)	<30	30-49	>50
Regurgitant orifice area (cm ²)	<0.1	0.1-0.29	>0.30
<i>Additional essential criteria</i>			
Left ventricular size		Increased	
Mitral Regurgitation			
<i>Qualitative</i>			
Angiographic grade	1+	2+	3-4+
Color Doppler jet area	Small, central jet (<4 cm ² or <20% LA area)	Signs of MR greater than mild present, but no criteria for severe MR	Vena contracta width >0.7 cm with large central MR jet (area >40% of LA area) or with a wall- impinging jet of any size, swirling in LA
Doppler vena contracta width (cm)	<0.3	0.3-0.69	≥0.7
<i>Quantitative (cath or echo)</i>			
Regurgitant volume (mL/beat)	<30	30-59	≥60
Regurgitant fraction (%)	<30	30-59	≥50
Regurgitant orifice area (cm ²)	<0.2	0.2-0.39	≥0.4
<i>Additional essential criteria</i>			
Left atrial size			Enlarged
Left ventricular size			Enlarged

B. Right-sided Valve Disease

Clinical Entity	Characteristic
Severe tricuspid stenosis	Valve area <1 cm ²
Severe tricuspid regurgitation	Vena contracta width >0.7 cm and systolic flow reversal in hepatic veins
Severe pulmonary stenosis	Jet velocity >4 m/sec OR maximum gradient >60 mm Hg
Severe pulmonary regurgitation	Color jet fills outflow tract; dense continuous-wave Doppler signal with a steep deceleration slope

*Valve gradients are flow-dependent and when used as estimates of severity of valve stenosis should be assessed with knowledge of cardiac output or forward flow across the valve.

ACC/AHA, American College of Cardiology/American Heart Association; AR, aortic regurgitation; cath, catheterization; echo, echocardiography; LA, left atrial/atrium; LVOT, left ventricular outflow tract; MR, mitral regurgitation.

Modified from Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease) developed in collaboration with the Society of Cardiovascular Anesthesiologists and endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. J Am Coll Cardiol 2006;48:e1-148.

Figure 32.1 Doppler-derived estimates of aortic valve area at ages 75, 80, and 85 years from a randomized sampling of individuals in the general population. Bars represent percentages of individuals with valve areas at or below the thresholds on the abscissa (in cm²). (Data from Lindroos M, Kupari M, Heikkilä J, et al: Prevalence of aortic valve abnormalities in the elderly: An echocardiographic study of a random population sample. *J Am Coll Cardiol* 1993;21:1220-1225.)

AORTIC STENOSIS

With the aging of the population, aortic stenosis (AS) has moved to the forefront in frequency of valvular heart disease encountered in older populations. The prevalence is surprisingly high; in patients 85 years of age, more than 8% of a random general population survey had Doppler-derived aortic valve area estimates of 1 cm² or less (Fig. 32.1),⁴ which is consistent with severe AS by the 2006 American College of Cardiology/American Heart Association (ACC/AHA) guidelines.⁵ Thus AS should be considered in the differential diagnosis of each elderly critical care patient with hemodynamic instability. The possibility of AS should be dismissed only after considering physical examination and electrocardiographic and, when applicable, echocardiographic and invasive findings, all of which have potential limitations in achieving accurate diagnosis as discussed subsequently.⁶

PATHOPHYSIOLOGY

AS represents a continuum, from hemodynamically insignificant congenital and atherosclerotic disease to end-stage decompensation secondary to severe valvular obstruction. The congenital pathway is typically secondary to a bicuspid aortic valve, the most common congenital cardiac anomaly if mitral valve prolapse is excluded, occurring in approximately 1.5% of the population⁷ and originally described by Da Vinci in 1513.⁸ The most common acquired anomaly is typically referred to as *degenerative disease*, an atherosclerotic process that represents a continuum from aortic valve sclerosis, which is not associated with a significant gradient, to a densely calcified aortic valve with severe outflow obstruction. Although the cause of aortic valve stenosis in patients undergoing aortic valve replacement (AVR) has shifted to

Figure 32.2 Distribution by age group of bicuspid versus tricuspid aortic valves in patients undergoing aortic valve replacement for aortic stenosis. (Modified from Roberts WC, Ko JM: Frequency by decades of unicuspid, bicuspid, and tricuspid aortic valves in adults having isolated aortic valve replacement for aortic stenosis, with or without associated aortic regurgitation. *Circulation* 2005;111:920-925.)

calcific tricuspid aortic valve disease from bicuspid and rheumatic disease, this remains an age-related phenomenon, with a predominance of bicuspid aortic valve disease in patients younger than age 70 (Fig. 32.2).⁹

AORTIC VALVE SCLEROSIS

Aortic valve *sclerosis* is an important disease entity, although usually not because of hemodynamic considerations. Defined as calcification and thickening of the aortic valve without significant outflow obstruction (gradient <20 to 25 mm Hg), it is present in nearly 30% of the population older than age 65 and nearly 50% by age 85¹⁰ and is associated with a 50% increase in 5-year cardiovascular mortality rate.¹¹ Its incidence is as high as 15-fold greater than aortic valve stenosis; the two diagnoses can be differentiated from one another by hemodynamics and physical examination findings discussed subsequently. In keeping with the primary atherosclerotic nature of aortic sclerosis, it is associated with increasing age, male gender, hypertension, smoking, elevated low-density lipoprotein and lipoprotein(a) levels, and diabetes.¹⁰ The primary importance of aortic valve sclerosis is that it provides a window on the overall presence of vascular disease, in particular coronary artery disease.¹² Thus there should be a high index of suspicion of vascular disease in any patient with aortic valve sclerosis managed in the critical care setting.

Patients with aortic sclerosis do progress to aortic valve stenosis; a study of more than 2000 patients with valve thickening showed progression to severe AS in 2.5% over an average time interval of 7 years.¹³ The fact that so-called degenerative disease of the aortic valve is absent in nearly half of octogenarians is also important to consider because it implies that it is not only aging but other factors that result in leaflet thickening, calcification, and stenosis. In the Helsinki Aging Study from which data are reflected in Figure 32.1, additional analysis demonstrated that not only age but also hypertension and low body mass index independently predicted calcification of the aortic valve, and age and

serum ionized calcium were independently associated with valvular stenosis.¹⁴ In general the process of sclerosis and then stenosis of the aortic valve appears, like atherosclerosis in general, to be an active inflammatory process, with deposition of lipoproteins, local inflammation with T lymphocyte and macrophage infiltration, fibroblast proliferation, and eventually osteoblast and bone formation.¹⁵ Similar to other vascular disease, endothelial disruption likely leads to the initial lipid deposition in the leaflet tissues. The areas of early focal plaque formation appear at the loci of greatest stress: on the aortic side of the leaflets at the flexion points. Because bicuspid valves have greater mechanical stress, the average age at presentation of patients with bicuspid aortic valve stenosis is significantly lower than in the tricuspid aortic valve stenosis that is typically seen in an elderly population.¹⁶

An important element in understanding calcific AS is lack of commissural fusion; unlike rheumatic mitral valve stenosis, in which fusion of the commissures is the primary cause of obstructive disease, lack of mobility of the aortic valve leaflets is the primary cause of obstruction in AS. Rheumatic AS is associated with commissural fusion but is now a rare finding, even in countries where rheumatic heart disease is prevalent, and is usually associated with mitral valve involvement and typically aortic insufficiency as well. More obscure causes, such as unicuspid and quadricuspid aortic valve disease, are uncommon, although presentation can be delayed to adulthood. In the case of unicuspid aortic valves there is a strong association with AS,¹⁷ whereas with quadricuspid aortic valves there is a high incidence of significant aortic insufficiency.¹⁸

Normal aortic valve area ranges from 3 to 4 cm². Significant resistance to outflow does not occur until the valve orifice is reduced more than 50%. Based on the simple hydraulic principle of Poiseuille's law, a 50% reduction in valve diameter results in approximately a 16-fold increase in resistance. In practice, as the resistance to outflow rises, the left ventricle is subject to pressure overload, resulting in compensatory hypertrophy. This in turn normalizes wall stress because the latter is proportional to chamber diameter times pressure divided by wall thickness (the LaPlace principle). The degree of wall thickness is variable: In patients with inadequate hypertrophic response, wall stress is inordinately high and there is early dilation and dysfunction.¹⁹ In patients with a profound hypertrophic response disproportionate to valvular resistance, wall stress actually falls below normal and ejection fraction (EF) becomes supranormal,²⁰ a phenomenon that appears to be more common in women with AS. The EF for any degree of wall stress is predictable,¹⁹ and patients who have disproportionately poor ejection phase indices (afterload mismatch) typically manifest left ventricular (LV) dysfunction beyond the depression that would be associated with high wall stress (Fig. 32.3),²¹ a phenomenon described under low-gradient, low-output AS that follows.

LV hypertrophy, although it reduces wall stress, has several features that may be deleterious. With progressive hypertrophy, diastolic pressures may rise as LV compliance decreases, resulting in increased LV filling pressures. In addition, the myocardial supply-demand relationship is deleteriously affected by hypertrophy in this setting. With increased wall stress and increased wall mass, myocardial oxygen demand

Figure 32.3 The relationship between ejection fraction and wall stress in patients with aortic stenosis. The patients (each represented by an "X") whose ejection fraction was disproportionately lower than the regression line had a poor overall outcome. In these patients ejection phase indices were depressed despite a low transvalvular gradient, a phenomenon suggesting intrinsic contractile dysfunction. (From Carabello BA, Green LH, Grossman W, et al: Hemodynamic determinants of prognosis of aortic valve replacement in critical aortic stenosis and advanced congestive heart failure. *Circulation* 1980;62:42-48.)

is increased; at the same time coronary flow reserve is decreased in AS,²² and in later stages of the disease diastolic perfusion pressure is lowered. Because of abnormal flow reserve, conventional testing for ischemia in the setting of significant aortic valve stenosis has inadequate specificity to identify the presence or absence of hemodynamically significant concomitant coronary artery disease.²³

Other features associated with AS that are important in the critical care setting include abnormal platelet function and decreased levels of von Willebrand factor,²⁴ with associated bleeding risk that improves with AVR. Another associated cause of bleeding is gastrointestinal angiodysplasia associated with aortic valve stenosis,²⁵ possibly exacerbated by the concomitant presence of von Willebrand syndrome.

The progression of AS is highly variable, but with the onset of moderately severe disease, the estimated mean decrease in valve area is on the order of 0.1 cm²/year.²⁶ Certain demographics and noninvasive findings appear to predict the rate of progression, including age older than 50 years and moderate to severe valve calcification.²⁷ The issue of progression is particularly important in patients who are asymptomatic of the disease because AVR before it is necessary is undesirable but must be weighed against the risk of sudden death. The latter has been studied in a number of longitudinal studies and is rare if patients are followed prospectively. The patients who are most likely to require early intervention are those with peak Doppler systolic velocities greater than 4 m/second or who have a rapid increase in serial transvalvular Doppler velocity measurements.^{26,27} This threshold has been confirmed by other series.²⁸ Once patients become symptomatic, with a classic triad of heart

failure, angina, or syncope, hemodynamic deterioration can be rapid with significant associated mortality risk.²⁹

DIAGNOSIS

PHYSICAL EXAMINATION

The hallmarks of the physical examination relate to the contour of the aortic pressure upstroke, with a low volume and delayed carotid upstroke (pulsus parvus et tardus), a late peaking systolic ejection murmur, and a diminished or absent aortic second sound. **Figure 32.4** demonstrates the hemodynamics that manifest in an abnormal carotid pulse contour; unlike the brisk upstroke of LV pressure over time (dP/dt), the aortic pressure is slow to rise and of significantly lower volume. An ejection click may be present in young patients with congenital AS, but with increasing calcification of the valve, mobility decreases to a point at which an ejection click becomes unlikely. The aortic component of the second heart sound, reflecting deceleration and closure of the aortic valve, is diminished or absent in severe AS when the thickened aortic valve leaflets are poorly mobile, have little deceleration, and drift rather than snap shut. The murmur of AS is characteristically a crescendo-decrescendo murmur that is late peaking, consistent with the timing of the peak gradient as seen in **Figure 32.4**, and is typically best heard over the right upper sternum and clavicle. It reflects the high-velocity systolic jet directed into the ascending aorta. A second component, described by Gallavardin as a musical component, is best heard at the left lower sternal border. The latter confounds diagnosis because the murmur is suggestive of mitral regurgitation (MR), but in its true form it is purely secondary to aortic valve stenosis. Because handgrip raises resistance to LV ejection, the murmur should decrease if it is a true Gallavardin phenomenon, whereas when it is secondary to MR, it should increase.³⁰

Unfortunately, none of these findings has sufficiently high sensitivity or specificity for AS or for differentiating moderate from severe disease.³ Many patients with AS, particularly the elderly with stiff noncompliant vessels, will have a wide pulse pressure even with declining cardiac output

and may have systolic hypertension. Hypotension may not be seen until late stages of the disease. The loudness of the murmur, which correlates to some degree with severity, is also not specific because body habitus and a variety of other factors affect the acoustics transmitted across the chest. Most importantly, in severe AS, as the cardiac output drops, the gradient generated decreases as well. In this setting the murmur may be quite soft, although sometimes still high pitched because of the high velocity across a tight constriction. A useful means of differentiating aortic sclerosis from stenosis is that in the former the systolic ejection murmur heard over the right sternum is typically midpeaking and mild to moderate in intensity, and it features a well-preserved aortic second heart sound. Although the physical findings described are variable, presence of the aortic second heart sound tends to exclude severe calcific AS.³¹

NONINVASIVE EVALUATION

In contrast to the physical examination, echocardiographic techniques have progressively improved over the past several decades and availability in the critical care setting in industrialized nations is ubiquitous. The characteristic echocardiographic features of AS are decreased valve leaflet mobility, calcification in all except congenital AS in adolescents and young adults, and an augmented Doppler velocity that generally allows accurate estimation of the gradient. In congenital bicuspid AS in young adults, when commissural fusion is dominant, a characteristic doming pattern is seen, but this disappears with progressive valve calcification. The severity of calcification correlates with extent of obstruction by middle age, and typically Doppler signal velocity with peak and mean pressure gradient and valve area by continuity equation provide an accurate overall assessment. However, the gradient is highly dependent on flow across the valve, and in low-output states the gradient may result in underestimation of severity of disease; in high-output states such as in patients with augmented cardiac output caused by inotropic stimulation, endogenous high catecholamine states, and sepsis, the gradient may be disproportionately higher than the severity of stenosis would suggest. The latest ACC/AHA guidelines describe the threshold for severe AS as antegrade

Figure 32.4 Left ventricular (LV), aortic (Ao), and left atrial (LA) pressure on 200 mm Hg scale, 100 mm/second paper speed. The aortic valve gradient is filled in yellow. The dramatic difference in the slope of left ventricular ($LV\ dP/dt$, dashed blue line) and aortic pressure upstroke ($Ao\ dP/dt$, dashed red line) and the low pulse pressure (≈ 30 mm Hg) in this patient with classic severe aortic valve stenosis is demonstrated.

jet velocity greater than 4 m/second, gradient greater than 40 mm Hg, and aortic valve area less than 1 cm², with the caveat that the gradient and jet velocity depend on the overall transvalvular flow⁵ (see Table 32.1). Importantly, antegrade flow across the aortic valve does not equal cardiac output in patients with confounding conditions, including aortic insufficiency; thus, for example, a patient with mild to moderate AS and moderate aortic insufficiency may have a transvalvular gradient suggestive of severe AS. Finally, although most practitioners do not index the valve area, it is important to appreciate that in patients with large body surface areas, disease that might be considered moderate in smaller patients may be functionally severe.

Several caveats need to be considered before acceptance of noninvasive data in the critical care setting. Inadequate acoustic windows in some patients and difficulty in positioning patients on respirators and with multiple lines in place do limit echocardiographic imaging. Technical errors in recording and interpretation result in significant misdiagnosis: errors in recording angle, inadvertent imaging of MR jets instead of aortic outflow, assessing proximal velocity instead of the transvalvular signal, and selecting signals in the setting of arrhythmias that are not representative of mean heartbeats can all lead to skewed assessment of valve disease severity.³² Further, a number of other potential confounding variables can lead to overestimation or underestimation of the severity of AS,^{6,33} and valve area calculations by the continuity equation in a low-flow setting may be inaccurate.³⁴ Because the continuity equation depends on measurement of the LV outflow track dimension, which is prone to inaccuracy, another measure of AS severity, the dimensionless index (the ratio of blood flow velocity across the LV outflow track to that across the aortic valve), has been widely adopted.³⁵ A number of other techniques for determining the severity of AS supplement the most commonly used noninvasive tools, including three-dimensional echo, computed tomography,³⁶ and magnetic resonance imaging (MRI).³⁷ Overall, there has been a major shift in the gold standard from catheter-derived to noninvasive-derived determination of AS severity, and cardiac catheterization is no longer indicated for hemodynamic assessment of aortic valve disease severity when noninvasive findings are unequivocal.⁵

The echocardiogram provides important additional information including severity of LV hypertrophy, LV function and size, and concomitant disease of other heart valves. The presence of regional wall motion abnormalities, in the absence of a conduction disturbance, suggests concomitant coronary artery disease. The electrocardiogram (ECG) in AS is typically abnormal and frequently features LV hypertrophy, with ST-segment abnormalities in the lateral leads typically described as a strain pattern.³⁸ Although occasionally mistaken for anterior ischemia or infarction, with loss of R voltage across the precordium and occasionally with narrow QS complexes, the ECG is not specific for severity of AS. With increasing calcification of the perivalvular tissues, heart block is seen, typically late in the course of the disease.

CARDIAC CATHETERIZATION

Cardiac catheterization is indicated in patients in whom the noninvasive data are equivocal, and coronary angiography

is indicated in a range of settings identified in Box 32.1. The hemodynamics of AS are best recorded with a catheter or catheters placed simultaneously on either side of the aortic valve.^{6,39} Unfortunately, most laboratories record femoral artery pressure in lieu of central aortic pressure or do a catheter pullback in lieu of simultaneous pressure tracings; both techniques can result in significant misinterpretation

Box 32.1 Indications for Cardiac Catheterization in Patients with Valvular Heart Disease

General Indications:

1. When noninvasive findings are inconclusive or discordant with clinical findings or inadequate imaging is obtained.
2. Right-sided heart catheterization when clinical decision making will be influenced by hemodynamics not otherwise obtainable.

Specific Indications for Coronary Angiography:

Class I

1. Before valve surgery or percutaneous balloon commissurotomy in patients with chest pain, other objective evidence of ischemia, decreased LV systolic function, history of CAD, or coronary risk factors.
2. In patients with apparently mild to moderate valvular heart disease but progressive angina, objective evidence of ischemia, decreased LV systolic function, or overt congestive heart failure.
3. Before valve surgery or percutaneous balloon commissurotomy in men 35 years and older, premenopausal women aged 35 years and older who have coronary risk factors, and postmenopausal women.

Class II

Surgery without coronary angiography is reasonable for patients requiring emergency valve surgery for acute valve regurgitation, aortic root disease, or infective endocarditis.

Class IIb

Coronary angiography may be considered for patients undergoing catheterization to confirm the severity of valve lesions before valve surgery without preexisting evidence of CAD, multiple coronary risk factors, or advanced age.

Class III

1. Coronary angiography is not indicated in young patients undergoing nonemergency valve surgery when no further hemodynamic assessment by catheterization is deemed necessary and there are no coronary risk factors, no history of CAD, and no evidence of ischemia.
2. Patients should not undergo coronary angiography before valve surgery if they are severely hemodynamically unstable.

Modified from Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease) developed in collaboration with the Society of Cardiovascular Anesthesiologists and endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. *J Am Coll Cardiol* 2006;48:e1-148.

CAD, coronary artery disease; LV, left ventricular. Class refers to ACC/AHA Guidelines classification system.

of the severity of aortic valve disease.⁴⁰ A variety of other errors in catheterization laboratory pressure measurements makes the catheter-derived valve area generally more variable than desirable in all except a few laboratories, including inherent errors in estimating rather than measuring oxygen consumption and in assuming that the Gorlin constant (originally established for a limited subset of patients⁴¹) and the valve area itself remain constant under varying loading conditions.³⁴ In the catheterization laboratory as well, transvalvular flow may be underestimated if there is concomitant aortic insufficiency, resulting in overestimation of the severity of aortic valve disease.

LOW-GRADIENT, LOW-OUTPUT AORTIC STENOSIS

The critical care unit patient with a low to moderate gradient (typically <30 mm Hg) across the aortic valve in the setting of low cardiac output represents an important conundrum (and should be differentiated from the aortic sclerosis patient with low gradient not associated with depressed output). In general, the rules of hydraulics demonstrate that valve area is proportional to flow divided by the square root of the gradient.⁴¹ Thus, when the valve area is fixed, increased flow is associated with an exponential rise in gradient when valve areas are less than 1 cm² (Fig. 32.5). When a patient in the critical care setting has depressed cardiac output and a low gradient across the aortic valve, there are two possible interpretations of these findings: either the patient has mild to moderate AS and poor LV function, or the patient has severe AS with a low EF appropriate to high wall stress (see Fig. 32.3) and secondary depression of cardiac output. In the case of the former, increasing flow results in better opening of the aortic valve, with only mild to moderate increase in gradient and an increase in the calculated valve area of 0.3 cm² or greater.⁴²

Figure 32.5 The relationship between transvalvular flow and transvalvular gradient for given valve areas. An exponential rise in gradient occurs when flow is increased with valve areas in the severe stenosis range (<1 cm²). The curve demonstrates that change in gradient is proportional to the square of change in flow; thus doubling the flow rate results in a fourfold increase in gradient. (From Gorlin R, Gorlin SG: Hydraulic formula for calculation of the area of the stenotic mitral valve, other cardiac valves, and central circulatory shunts. *Am Heart J* 1951;41:1-29.)

In the latter case, a fixed obstruction to outflow exists and increasing transvalvular flow results in a dramatic increase in gradient. In addition to increasing flow across the valve in these patients, typically with dobutamine infusion,⁴³ the echocardiogram can be useful in several other ways⁴⁴: valve calcification is suggestive of fixed outflow obstruction and, if severe, suggests that the underlying disease is severe AS rather than LV dysfunction. Preserved LV contractile reserve, with significant rise in stroke volume (>20%), peak velocity (>0.6 m/second), or mean transvalvular gradient (>10 mm Hg) at the time of dobutamine infusion is an additional useful marker. Lack of contractile reserve has been associated with lower operative survival rate⁴⁵ (6% vs. 33% in one study), although it should not be the sole parameter for the decision on whether or not to perform AVR: patients who survive may manifest significant recovery in LV function postoperatively.⁴⁶ Low contractile reserve should not preclude AVR in patients who do have severe fixed obstruction because their prognosis without surgery is abysmal.⁴⁷ One other variation of low-gradient low-output AS involves patients with small hypertrophied ventricles and preserved EF. This subset, sometimes called *high valvuloarterial impedance AS*, has low gradient because of low stroke volume; the burgeoning evidence base does show improved results with AVR.⁴⁸

THERAPY

MEDICAL MANAGEMENT

Medical management is aimed solely at patient stabilization because pharmacologic intervention has never been shown to prolong life and can achieve modest hemodynamic improvement at best. In the critical care setting the approach to the patient with AS normally parallels treatment of corresponding degrees of heart failure, albeit with caution, because the normal therapeutic approach to heart failure can be deleterious or fatal in the setting of severe AS. The traditional heart failure therapies, in particular, diuretics and vasodilators, need to be used with care because reduction in preload can cause hypotension, decreased cardiac output, and a downward spiral into refractory shock. In patients with small-volume hypertrophic left ventricles, cardiac output is particularly preload dependent.

Atrial arrhythmias, in particular, atrial fibrillation (AF), can lead to abrupt and severe decompensation because of loss of the atrial contraction component of LV filling. Cardioversion in the critical care setting is particularly helpful in severely decompensated patients, and maintenance of sinus rhythm in patients who are otherwise suitable (e.g., left atrium <6 cm, recent onset of AF, and absence of clot in the left atrium by transesophageal echocardiography) should be a priority.

Despite the caveats, vasodilator therapy, including nitroprusside, has been used in the critical care setting in patients with severe LV dysfunction and severe AS.⁴⁹ In a select group of patients not dependent on inotropes, cardiac output rose significantly and there was overall hemodynamic improvement. Similarly, intra-aortic balloon pumping has been used, although there are only isolated case reports of efficacy.^{50,51} As would be expected, both nitroprusside and intra-aortic balloon pumping result in afterload reduction and

some increase in transvalvular flow along with some increase in aortic valve gradient.

Hemodynamic monitoring is essential for the pharmacologic management of decompensated severe AS patients in the critical care setting. Because of the dependence on preload, a fine threshold exists between optimal filling pressures and pulmonary edema. Vasodilator therapy as described earlier results in peripheral vasodilation, but because of the fixed obstruction to outflow it may not provide sufficient increase in stroke volume and cardiac output to maintain systemic blood pressure. Inotropic agents are frequently required, and patients with inadequate contractile reserve may show limited improvement. Beta blockers are relatively dangerous, although tachycardia is hemodynamically unfavorable, even in sinus rhythm. Beta blockade, if employed, should be used with great caution. Beta blockers decrease contractility and, in addition, an increase in heart rate may be the only remaining compensatory mechanism for low stroke volume because of the fixed resistance to outflow. Patients with severe AS can enter a “death spiral” in which hemodynamic recovery becomes impossible.

Lipid-lowering therapy and converting enzyme inhibitors have been the subject of substantial investigation,⁵² although their role is in the chronic setting rather than during critical care. Two prospective randomized trials failed to show clear benefits of a statin^{53,54} in slowing disease progression. Some preliminary evidence suggests potential benefits of angiotensin-converting enzyme (ACE) inhibitors in decreasing progression of aortic valve calcification,^{55,56} but the available clinical data do not show slowing of AS progression.⁵⁷ Both lipid-lowering and converting enzyme inhibitors need to be tested in larger populations earlier in the course of aortic valve disease.

PERCUTANEOUS INTERVENTIONS

Balloon Valvuloplasty

Balloon aortic valvuloplasty is a temporizing measure for patients who are hemodynamically unstable and are at high risk for AVR. Although the procedure is therapeutic and indicated in congenital AS in children and young adults, the risk/benefit ratio in patients beyond their 20s is usually unfavorable. Because calcific AS is associated with open commissures and ossified leaflets, abrupt balloon inflation exerts its effect by improving leaflet compliance through the formation of multiple, usually microscopic, fracture lines in the calcified tissues. Stretching of the commissures is temporary, and any hemodynamic benefit of the latter resolves within hours. The leaflets lose their improved compliance within weeks to months, and the aortic valve area typically returns to baseline.

The acute hemodynamic results (Fig. 32.6) are poor compared with those of AVR, with a 50% reduction in gradient and an increase in aortic valve area of only 0.2 to 0.3 cm².⁵⁸ The in-hospital mortality rate was close to 10% in the National Heart, Lung and Blood Institute registry⁵⁹ and is substantially higher in patients with hemodynamic decompensation and multiorgan failure. Most valves have restenosed within a few months, with a recent series showing an 87% mortality rate after a median period of less than 7 months,⁶⁰ and no benefit for long-term outcomes has been

A

B

Figure 32.6 Hemodynamic response to percutaneous balloon aortic valvuloplasty. Tracings show before (A) and after (B) balloon dilation on 200 mm Hg scale. A successful 50% reduction in gradient occurs, but residual gradient remains 50 mm Hg, still in the severe category. The pulse pressure has increased from 60 mm Hg to 90 mm Hg, the peak aortic systolic pressure has increased to 140 mm Hg from 100 mm Hg, and the left ventricular pressure upslope can be seen to have improved dramatically. Ao, aorta; LA, left atrium; LV, left ventricle.

shown. Indeed, the overall clinical course is not influenced by balloon valvotomy.⁶¹ Nevertheless, it can serve as a bridge to transcatheter AVR or surgical AVR in select patients with multiple comorbid conditions and is an alternative but low efficacy measure for patients who are not candidates for AVR. It is not an alternative to TAVR or surgery for patients who can undergo valve replacement, even for most patients at relatively high risk for the latter.

Several settings in which balloon aortic valvuloplasty was previously considered to have a role are no longer included as indications in the 2006 ACC/AHA guidelines.⁵ These settings include preoperative balloon dilation in patients undergoing noncardiac surgery⁶²; in general all but decompensated patients can withstand general anesthesia as long as careful hemodynamic monitoring and anesthesia management are performed.⁶³ Patients who require urgent noncardiac surgery in the setting of severe symptomatic AS do have a significant perioperative risk,⁶⁴ and preoperative AVR should be considered if at all possible. Balloon aortic valvuloplasty has also been proposed as a tool to differentiate myocardial dysfunction from severe AS with secondary LV dysfunction in low-gradient, low-output AS.⁶⁵ The latter patients typically demonstrated substantial improvement in stroke volume and EF after balloon dilation, but

dobutamine stress testing is a far safer, less morbid screening tool.

Transcatheter Aortic Valve Replacement

Transcatheter aortic valve replacement (TAVR), a technology developed in the past decade, has revolutionized the treatment of AS. The procedure is of increasing importance in the critical care setting. Tissue valves are sewn to either balloon expandable or self-expanding stents, which are crimped onto a catheter and advanced across the stenotic native valve. Both balloon expandable (Fig. 32.7) and self-expanding technologies are widely available outside the United States. The landmark PARTNER (Placement of AoRtic TraNscathetER valves) study had two cohorts: PARTNER A enrolled high-risk but operable patients while PARTNER B enrolled patients deemed inoperable. PARTNER A randomized patients to surgical aortic valve replacement (SAVR) versus two types of TAVRs: transfemoral if the iliac and femoral vasculature was suitable for accommodating the large catheter shafts or transapical if not.⁶⁶ The results of TAVR and SAVR were similar, including mortality rate, stroke, and quality of life with published follow-up through 2 years; vascular complications were higher with TAVR and major bleeding and AF were higher

Figure 32.7 Percutaneous aortic valve shown in place immediately after transcatheter deployment with the balloon still inflated. (From Smith CR, Leon MB, Mack MJ, et al: Transcatheter versus surgical aortic-valve replacement in high-risk patients. *N Engl J Med* 2011;364:2187-2198.)

Figure 32.8 Results of the Placement of Aortic Transcatheter Valves (PARTNER) Trial. **A**, Death from any cause or stroke in the A cohort, the high-risk but operable patients who were randomized to surgical aortic valve replacement ($n = 351$) versus either transfemoral ($n = 244$) or transapical ($n = 104$) transcatheter deployment depending on the suitability of the femoral and iliac circulation. There were no differences in mortality rate or stroke. **B**, Mortality in the B cohort, showing substantial survival advantage among the 179 patients undergoing transcatheter aortic valve replacement over the 179 patients treated with medical therapy. (A from Smith CR, Leon MB, Mack MJ, et al: Transcatheter versus surgical aortic-valve replacement in high-risk patients. *N Engl J Med* 2011;364:2187-2198; B from Makkar RR, Fontana GP, Jilaihawi H, et al: Transcatheter aortic-valve replacement for inoperable severe aortic stenosis. *N Engl J Med* 2012;366:1696-1704.)

with SAVR⁶⁶ (Fig. 32.8A). PARTNER B randomized patients with suitable vasculature to transfemoral TAVR versus medical therapy.⁶⁷ Patients who received only medical therapy (with or without balloon valvuloplasty) had a 51% 1-year mortality rate compared to those inoperable patients randomized to TAVR who had a 31% 1-year mortality rate, an approximately 40% relative reduction (Fig. 32.8B). Thus, TAVR appears to be among the most dramatically successful of all modern cardiac interventions. However, it is noteworthy that the residual mortality rate in the inoperable TAVR patients remains very high, reflecting the severe comorbid conditions in patients who met inoperability criteria. There was also an initially higher stroke risk in the TAVR patients.⁶⁷ The risk of stroke in follow-up appears to be largely related to patient comorbid conditions that increase stroke risk, rather than the type of valve replacement.⁶⁸ The dramatic mortality risk benefit with TAVR in inoperable patients has been shown to continue through 2 years of follow-up; because the stroke risk is higher in the surviving medically treated population, the early excess stroke risk associated with TAVR largely resolves by 24 months.⁶⁹ Outside the United States, TAVR has been performed in some 70,000 patients; the Food and Drug Administration initially approved TAVR for inoperable patients based on the results of PARTNER B and subsequently approved the high-risk population treated in PARTNER A. A variety of investigational uses of the TAVR platform, such as valve-in-valve replacement for patients with bioprosthetic valve dysfunction (AS and aortic insufficiency) are being performed, primarily outside the United States⁷⁰; the possibility that transcatheter valve-in-valve replacement will eventually supplant reoperation may change the algorithm for choice of tissue versus mechanical AVR.

The management of TAVR patients after valve replacement frequently takes place in the critical care unit. The higher rate of vascular complications associated with TAVR requires careful monitoring for limb ischemia, retroperitoneal hemorrhage, and a variety of other vascular

complications.⁷¹ Conduction disturbances, particularly after use of a self-expanding TAVR platform, occur in a significant percentage of cases, requiring permanent pacemaker placement.⁷² A number of issues, such as the use of dual antiplatelet therapy and anticoagulation after TAVR remain to be fully investigated; most operators treat with dual antiplatelet therapy for periods ranging from 1 to 6 months; dual antiplatelet therapy plus anticoagulation for patients with AF is a combination with particularly high major bleeding risk, though the evidence base is incomplete, and many clinicians use only aspirin and warfarin in this setting.

Aortic Valve Replacement

AVR remains the treatment of choice for severe AS in patients who are considered to have reasonable operable risk. Class I indications are severe AS (valve area less than 1 cm²) with symptoms or, regardless of symptoms, if patients have severe AS and are undergoing coronary artery bypass, are undergoing surgery of the aorta or other heart valves, or have LV dysfunction. A long list of class II indications generally focuses on patients who do not meet class I criteria but are thought to be at increased risk of rapid disease progression or hemodynamic compromise. In addition, patients with moderate AS who undergo other cardiac surgery generally have simultaneous AVR. Survival after AVR is excellent if LV function is preserved, with operative mortality rate in ideal candidates as low as 1%. In these patients, age-matched survival is not significantly different from patients without AS.⁷³ In the setting of LV dysfunction, however, postoperative life expectancy is relatively poor.⁷⁴ Nevertheless, conservative therapy for severe AS remains an undesirable alternative: A recent review of 453 patients treated without intervention despite severe AS had 1-year, 5-year, and 10-year survival rates of only 62%, 32%, and 18%, respectively,⁷⁵ with the worst survival in patients with renal failure, pulmonary hypertension, age older than 75 years, diminished EF, and congestive heart failure.

AORTIC INSUFFICIENCY

The overall prevalence of moderate or severe aortic insufficiency (AI) in the United States, as shown in the Framingham Offspring Study, ranged from 0.3% in the fifth decade of life to 2.2% for patients aged 70 to 83.⁷⁶ The frequency is age and male gender related. The diagnosis of AI is more difficult and the treatment issues in many ways more complex than for AS, with less of a clear dichotomy in the decision tree for valve replacement. AI needs to be considered in light of its acuity: Acute AI is usually associated with life-threatening comorbid conditions and the resultant acute regurgitation places great stress on the left ventricle and may itself be fatal. In contrast, chronic AI may evolve from clinically insignificant to requiring surgery over decades. Unlike AS, it is not primarily a disease of the aging process (although it does occur more frequently with increasing age) and is typically secondary to one of an extensive list of systemic or structural diseases that result in insufficiency of the aortic valve. Acute AI frequently requires urgent surgery, whereas chronic AI may be managed by watchful waiting and some limited options for medical therapy.

PATHOPHYSIOLOGY

Acute AI is generally associated with leaflet involvement by endocarditis or disruption of the aortic valve's annular structure by dissection or trauma. Chronic AI, by contrast, is caused by congenital valve abnormalities, most importantly bicuspid aortic valve disease, or by the degenerative process described earlier associated with AS. Conditions that distort the annulus and aortic root including systemic hypertension have been considered to be important causes of secondary AI, although the association between chronic AI and systemic hypertension remains to be confirmed.^{76,77} Rheumatic AI, almost invariably associated with mitral valve involvement as well, remains prevalent in developing countries but is an uncommon cause of AI in industrialized nations.

In general, causes of AI (Box 32.2) have been divided into those that affect the leaflets primarily and those that affect the root and annulus. The former includes bicuspid and other aortic valve abnormalities, endocarditis, rheumatic aortic valve disease, the atherosclerotic process described earlier, connective tissue disorders, antiphospholipid syndrome (Libman-Sacks endocarditis), and toxicity from anorectic drugs.⁷⁸ The aortic root and annulus are affected by a variety of comorbid conditions that dilate the aortic root; Marfan and Ehlers-Danlos syndromes; osteogenesis imperfecta; chronic aortic dissection; syphilitic aortitis; connective tissue disorders; and, along with the valve leaflets, ankylosing spondylitis.

In isolated acute AI, the sudden onset of regurgitation imposes a large-volume load on the left ventricle in diastole prior to an adaptive process being in place. The abrupt rise in pressure is reflected by parallel development of left atrial and pulmonary vascular hypertension, frequently resulting in pulmonary edema. Because the compliance of a previously unaffected left ventricle is not sufficient to allow adequate dilation to absorb the regurgitant volume, the ventricle operates on the steep portion of its pressure-volume curve,

Box 32.2 Etiology of Acute and Chronic Aortic Insufficiency

with inadequate stroke volume to accommodate the high regurgitant flow. The effective (net) forward stroke volume (antegrade flow minus retrograde filling) is therefore low, compensated to some degree by tachycardia, but frequently insufficient to maintain normal cardiac output. This phenomenon is exaggerated in patients with preexistent LV hypertrophy in whom the ventricle is already operating on the steep portion of its pressure-volume curve, and particularly severe decompensation is seen when the left ventricle is small and hypertrophic. Critical care settings for the latter unfortunately include many of the common scenarios for acute AI including endocarditis in the setting of AS and aortic dissection in patients with hypertension and a dilated aortic root.⁵

Acute severe AI results in near approximation of aortic and LV pressures at end diastole, with consequent deleterious effects on coronary perfusion of the subendocardium (Fig. 32.9). Because coronary perfusion pressure is the difference between diastolic pressure in the aortic root and subendocardial pressure in the LV cavity, the decrease in aortic diastolic pressure and rise in subendocardial pressure that are hallmarks of acute AI can result in profound subendocardial ischemia, especially in patients with preexistent hypertrophy or patients with underlying coronary artery disease. In addition, because afterload and wall stress in this setting are increased, there is a rise in myocardial oxygen demand simultaneous with a fall in supply, occasionally leading to cardiogenic shock and death. Acute AI also results in early closure of the mitral valve as LV diastolic pressure rises above left atrial pressure, a phenomenon that has potential protective benefits for the pulmonary circulation.

Figure 32.9 The hemodynamics of acute aortic insufficiency. The wide pulse pressure (150 mm Hg) difference between peak and minimum aortic pressure (blue arrow) and near diastasis of left ventricular and aortic pressure late in diastole (red arrow) are demonstrated. Ao, aorta; LV, left ventricle. (Modified from Grossman W: Profiles in valvular heart disease. In Baim D [ed]: Grossman's Cardiac Catheterization, Angiography and Intervention. Philadelphia, Lippincott Williams & Wilkins, 2006, p 654.)

In contrast, chronic AI features a host of adaptive processes by the left ventricle including progressive dilation, increased compliance, and hypertrophy. As with AS, hypertrophy results in lower wall stress but AI features an increase in afterload combined with progressive LV dilation and somewhat less hypertrophy, resulting in significantly higher wall stress than seen in compensated AS.⁷⁹ End-diastolic dilation of the left ventricle allows for larger stroke volumes to compensate for regurgitant fractions, which may be in the range of 50% or greater. With combined pressure and volume overload, unique among the valve disorders discussed in this chapter, LV adaptations allow for maintenance of normal overall function until ventricular remodeling and hypertrophy are no longer sufficient to maintain forward stroke volume and EF. With increasing wall stress and LV dilation, LV contractility is eventually impaired, at which point filling pressures begin to rise (or rise further) and patients become symptomatic. Coronary flow reserve in AI, as with AS, is impaired⁸⁰ and, combined with increased demand and the need for additional perfusion for a hypertrophic myocardium, may result in significant ischemia. The onset of symptoms may be abrupt, especially with new onset of atrial tachyarrhythmias or sudden increase in cardiac output demand such as with exertion or infection.

Although acute AI represents a relative or absolute medical emergency, chronic AI may have an insidious course over decades. Some insight into the rate of progression of chronic AI is provided by a meta-analysis incorporated into the most recent ACC/AHA guidelines.⁵ In a review of nine admittedly heterogeneous studies incorporating nearly 600 primarily asymptomatic or mildly symptomatic patients with AI, average progression to symptoms with or without LV systolic dysfunction was 4.3% annually, and sudden death occurred in 0.2% annually.⁵ Although this rate of progression is modest, patients do not necessarily

develop symptoms before developing LV dysfunction or sudden death.⁸¹ Age, end-systolic dimensions,⁸² and rate of deterioration of end-systolic dimension and EF⁸³ are more sensitive tools for predicting outcome in chronic AI.

In contrast, in the setting of *symptomatic* AI that does not fall in the acute severe category, an annual mortality rate of 6% to 25% has been described, depending on severity of symptoms. By the 10-year follow-up, 75% had undergone AVR or died.⁸⁴

DIAGNOSIS

PHYSICAL EXAMINATION

The hallmarks of *acute* severe AI include features consistent with congestive heart failure and low cardiac output including tachycardia, dyspnea, and signs of impaired cardiac output such as peripheral vasoconstriction. The wide pulse pressure that is a hallmark of AI may or may not be seen, in part because it is dependent on LV compliance. The classic AI murmur may not be heard because of the limited gradient between the aorta and left ventricle during diastole when LV diastolic pressures in some cases approach systemic diastolic pressures. Tachycardia and diminished effective forward flow in acute AI may offset the augmented systolic and wide pulse pressure seen in later stages of the disease, and these patients may have normal or occasionally diminished pulses, although more moderate acute AI may feature the more classic findings. Early closure of the mitral valve may result in a soft first heart sound, and distortions of leaflet anatomy may result in lack of a distinct aortic second heart sound. In some cases absence of a second heart sound in a patient presenting with cardiogenic shock may be the most prominent physical finding.⁷⁸

The dramatic physical findings in *chronic* AI are among the most familiar to physicians and trainees. A wide pulse pressure results primarily because of increased stroke

volume, which augments systolic pressure,⁸⁵ and low aortic diastolic pressures because of volume runoff into the left ventricle. This in turn results in a large variety of associated eponymous physical findings including bounding carotid and peripheral pulses (Corrigan's and water hammer pulses, respectively); Hill's sign (dramatically higher systolic pressure in the legs than the arms because of the exaggerated effect of harmonics on systolic pressure waveforms, variously described as having a 20 or 40 mm Hg threshold); Duroziez's sign (to and fro murmur over the femoral arteries); and Traube's sign ("pistol shot" sound over the femoral artery during simultaneous compression). With LV dilation, the apical impulse is displaced laterally.

The intensity of the classic diastolic decrescendo murmur heard over the left midsternal border generally correlates well with the severity of AI,⁸⁶ although in later stages of decompensation (or in acute AI), when the gradient between the aorta and the left ventricle disappears in later stages of diastole, the murmur typically shortens. When the murmur is better heard over the right (rather than left) sternal border, the cause of the AI may be secondary to a dilated aortic root rather than a primary leaflet abnormality.⁸⁷ Two other murmurs are frequently heard with moderate to severe AI: a systolic ejection murmur consistent with increased transvalvular flow and on occasion an Austin-Flint murmur. The latter is the apical diastolic rumble occasionally confused with mitral stenosis and thought to originate from vibration of the anterior mitral leaflet caused by the diastolic regurgitant jet originating at the aortic valve; it has been described only in the setting of severe AI.⁸⁷ In rheumatic AI, if a diastolic rumble is heard, mitral stenosis should be excluded. An S₃ gallop is most likely to be present when severe AI occurs in a setting of depressed LV function⁸⁸ but may merely reflect substantial volume loading; the finding is not specific.

NONINVASIVE EVALUATION

As with AS, noninvasive assessment has replaced cardiac catheterization for determining severity of AI. It provides both structural and physiologic information including visualization of the leaflets, annulus, and aortic root; semiquantitative assessment of the severity of AI; and characterization of LV size, hypertrophy, and function, as well as other structural heart disease. Transesophageal echocardiography has superior diagnostic sensitivity to transthoracic echo for certain parameters, in particular for detection of valvular vegetations.⁸⁹ A wide range of techniques for measurement of AI severity including width of the color Doppler jet compared with size of the LV outflow tract, width of the vena contracta, regurgitant volume, regurgitant fraction, and regurgitant orifice area are described in Chapter 8. The correlation of these parameters with severity of AI is listed in Table 32.1. Additional findings of importance are rate of jet velocity deceleration as diastasis is achieved between aortic and LV diastolic pressures and duration of diastolic flow reversal in the aorta.⁹⁰ In addition to echocardiography, cine MRI can assess severity of AI, size of chamber volumes, LV mass, wall thickness, and systolic function.⁹¹ LV size and function have also been followed serially by radionuclide ventriculography.⁹²

The size and function of the LV have been used to set thresholds at which AVR should be considered. The ACC/

AHA guidelines⁵ and the European Society of Cardiology guidelines⁹³ have set slightly different values for class I and II recommendations. The echocardiogram-based recommendations, which vary with clinical settings, use thresholds that include LV end-diastolic dimension greater than 70 to 75 mm and end-systolic dimension greater than 50 to 55 mm, aortic root dimension greater than 50 to 55 mm (the lower threshold is for patients with bicuspid valves or Marfan syndrome),⁹³ and EF less than 50%. As the observational data have grown, these numbers have shifted slightly from the familiar "rule of 55s," which recommended surgery for asymptomatic patients with EF less than 55% or LV end-systolic dimension greater than 55 mm. An important consideration is that the end-systolic and end-diastolic dimensions should be adjusted downward for patients with small body surface area. Keeping in mind that these threshold values can be confounded by comorbid conditions that affect chamber size and function including ischemic and other forms of cardiomyopathy, as well as multivalvular disease, is important.

The ECG was once an important tool in the serial assessment of patients with AI. Similar to AS, features of LV hypertrophy may be present. Progression of LV dilation and dysfunction were thought to correlate with development of an LV strain pattern, a phenomenon that has been confirmed.⁹⁴ As a result, the use of digitalis glycosides, which can cause a similar strain pattern, was discouraged in order to maintain relative specificity of the finding. Conduction disturbances remain an important feature, particularly heart block in the setting of endocarditis, discussed subsequently.

CARDIAC CATHETERIZATION

As with the other valvular diseases discussed in this chapter, cardiac catheterization is indicated only for patients with inconclusive noninvasive findings or when noninvasive findings are discordant with the rest of the clinical picture. Typical findings include a wide aortic pulse pressure and an exaggerated rise in LV diastolic pressure, reflecting continuous retrograde filling during diastole (see Fig. 32.9). Cardiac catheterization in this setting normally includes aortic root angiography; although the latter requires a significant dye load (typically 30 mL/second for 2 seconds) to be diagnostically accurate. The hallmark of severe AI is greater opacification of the left ventricle than the aorta. The indications for coronary angiography in this setting are listed in Box 32.1.

THERAPY

MEDICAL MANAGEMENT

In acute AI, medical therapy is targeted to stabilization pending AVR. Nitroprusside has been the standard for reducing peripheral vascular resistance and improving net forward flow across the aortic valve since the 1970s.⁹⁵ The use of arterial vasodilators is more complex when the patient is already hypotensive, and a combination of inotropes and afterload reduction should be considered. Although afterload reduction in this setting is highly beneficial, the otherwise optimal combination of afterload reduction and augmented pressure normally provided by intra-aortic balloon pumping in cardiogenic shock (see Chapters 7 and 30) is not a viable choice in AI. Counterpulsation during

diastole increases the severity of AI with potentially catastrophic consequences; it represents an absolute contraindication to the intra-aortic balloon pump.

Besides vasodilator therapy, maneuvers to raise the heart rate may be helpful, especially in patients who are bradycardic or have a normal heart rate. Tachycardia disproportionately decreases the diastolic filling period, thereby decreasing the duration of regurgitation across the aortic valve. Both isoproterenol or electrical pacing to raise the heart rate have been used with therapeutic benefit.

In *chronic* AI, the evidence base is incomplete and somewhat controversial. The general consensus is that asymptomatic patients with mild to at most moderate AI with normal LV function who are not hypertensive do not require or benefit from vasodilator therapy.^{81,83} Only when patients are not surgical candidates is vasodilator use in chronic AI a class I indication.⁵ Class II indications are short-term treatment to optimize the patient's hemodynamic status prior to AVR and, more controversially, long-term therapy for asymptomatic patients with severe AI but preserved LV function. Two important studies with divergent results have been performed: One, using nifedipine, appeared to demonstrate some slowing of progression to need for AVR compared with patients on digoxin.⁹⁶ The second, a placebo-controlled study, failed to demonstrate clear benefits of vasodilator therapy with either nifedipine or an ACE inhibitor,⁹⁷ but there are concerns regarding the size of the study, dose of drug used, and modest severity of disease at baseline. Oral vasodilators that have been described as having potential therapeutic benefit include several dihydropyridine calcium channel blockers (nifedipine and felodipine), as well as hydralazine. The appropriateness of vasodilator therapy regardless of severity of disease is clearer in patients with systemic hypertension, in whom reduction of afterload has dual benefits. The dose of drug should be sufficient to show at least some reduction in systolic pressure. There is no evidence base to recommend other forms of medical therapy, such as nitrates or drugs commonly used to treat congestive heart failure to prevent progression of disease in chronic asymptomatic AI. In the critical care setting, however, inotropes and vasodilators are appropriate if patients have congestive heart failure or a low output state, or both.

AORTIC VALVE REPLACEMENT

Two factors primarily determine when a patient should be referred for valve replacement: the presence of symptoms and findings of LV systolic dysfunction.⁵ Surgery results in superior long-term survival than medical therapy alone for symptomatic patients.^{84,98} Similarly, patients with LV dysfunction have an inverse correlation between EF and mortality risk.⁹⁹ Three ACC/AHA class I indications for surgery, all for patients with severe AI, exist: (1) patients who have symptoms regardless of LV function; (2) patients with LV systolic dysfunction (EF less than or equal to 50%) regardless of symptoms; and (3) patients undergoing coronary bypass surgery or surgery on other heart valves or the aorta.

ACC/AHA class II indications use the thresholds defined by LV dimensions, again for patients with severe AI, using 55 mm as the end-systolic threshold and 75 mm as the end-diastolic threshold, but lowering those values by 5 mm when the rate of LV dilation is progressive or when patients have

Figure 32.10 Vegetation (arrow). On right is wide-open aortic insufficiency—the jet fills the outflow tract. Asterisk on left refers to walled-off echolucent abscess cavity. LA, left atrium; LV, left ventricle.

deteriorating exercise tolerance or an abnormal hemodynamic response to exercise. Patients with only moderate AI who are undergoing surgery on the aorta or coronary bypass are also considered to have class II indications.

The question of whether it is ever too late to perform AVR in patients with AI has been raised.⁸⁵ Because the disease involves high afterload and wall stress, there is postoperative improvement in EF¹⁰⁰ even in patients with severe baseline LV dysfunction. In general there is substantial reversal of the physiologic adaptations required by chronic severe AI in the postoperative state.¹⁰¹ Nevertheless, delay in referring patients for surgery is deleterious, with significant negative impact on outcomes¹⁰²; the prognosis is adversely affected both by the severity and duration of LV dysfunction.¹⁰³ This includes a fourfold increase in operative mortality rate for patients with EF less than 35% (14%) compared with those with EF greater than 50% (3.7%). Thus the trend has been for earlier referral of symptomatic patients and more aggressive noninvasive monitoring for early detection of deterioration in LV function or dimensions.

Special consideration should be given to patients with acute aortic valve endocarditis. Deteriorating hemodynamics, as well as extension of infection as manifest by progressive heart block and ring abscess formation on echo (Fig. 32.10), are among several factors that mandate early surgery¹⁰⁴; despite the semiselective nature of the operation (with an operative mortality rate close to 10%) and the theoretical risk of an infected prosthesis, the long-term outcomes have been satisfactory, with 75% 10-year survival rate after hospital discharge.¹⁰⁵

MITRAL REGURGITATION

Anatomically and physiologically, the mitral valve is the most complex of the heart valves, dependent for function on a complex interaction between leaflets, annulus, commissures, and the supporting apparatus consisting of chordae tendineae tethered to the papillary muscles (Fig. 32.11). Distortion or dysfunction of any of the elements and changes

Figure 32.11 Structure of the mitral valve, its surrounding apparatus, and relationship to the left ventricle. Each component can contribute to the presence and extent of mitral regurgitation. (From Otto CM: Evaluation and management of chronic mitral regurgitation. *N Engl J Med* 2001;345:740-746.)

in function and geometry of the left ventricle and left atrium can all have a significant impact on flow across the mitral valve. In addition, unlike other valvulopathies, the mitral valve is highly dependent on the myocardial circulation. In contrast with the relatively passive nature of opening and closing of the aortic valve, mitral valve motion is an active process reflecting not just cyclic pressure variations but also tethering and dynamic interaction with the supporting apparatus. As with AI, mitral insufficiency (MR) has acute and chronic manifestations and chronic (rather than acute) insufficiency is more common. However, acute MR has a much larger variety of causes than acute AI and the overall incidence is higher. Data from the Framingham Offspring Study revealed a prevalence of moderate or greater MR from 0.9% of women in the fifth decade of life, to 11.2% of men between ages 70 and 83, and correlated with age, low body mass, and systemic hypertension.⁷⁶ As with AI, ventricular function predicts overall outcomes. Chronic MR can both cause and be the result of LV remodeling and heart failure and, when secondary to LV dysfunction, is associated with a significantly poorer overall prognosis than LV dysfunction without secondary MR.¹⁰⁶

PATHOPHYSIOLOGY

Fundamental understanding of the pathophysiology of MR has expanded substantially in the past 2 decades. In particular, awareness of the role of the subvalvular apparatus in preserving LV function and data demonstrating the need for earlier referral to surgery have resulted in significant

changes in clinical and surgical practice, leading to substantial improvement in outcomes.¹⁰⁷

As with AI, MR results in volume overloading of the LV. Unlike AI, the afterload is not increased and overall LV ejection is enhanced rather than impaired by loading conditions, although in significant MR half or more of the ejection is retrograde into the left atrium. The incompetent mitral valve acts as a second pathway for blood ejection, which reduces afterload in a setting in which preload is increased, thus potentiating ejection via the Frank-Starling mechanism. The combination ultimately may raise EF to supranormal early in the course of the disease. As a result, patients with “normal” EF may already have significant impairment in LV function.¹⁰⁸ Adaptations to the volume loading include lengthening of the myocytes, which increases LV volume. Progressive MR eventually results in contractile dysfunction. Relatively early in the course of the disease, the sympathetic nervous system is activated as a compensatory mechanism to volume loading and decreased forward ejection.¹⁰⁹ Chronic high sympathetic tone results in secondary myocardial damage¹¹⁰ and has been postulated as the rationale for potential benefit from beta blockade in chronic MR.¹¹¹ Over time, although some hypertrophy develops, the predominant response to volume overload without pressure overload is enlargement of chamber size. Extrapolating the LaPlace relationship, which is manifestly protective of wall stress in AS, the progressive expansion of LV dimensions in MR without similar compensatory hypertrophy results in increasing wall stress, which in turn results in increasing MR. In a similar manner, a second vicious

circle is caused by the effect of MR on LV chamber size, which, as it enlarges, results in stretching of the annulus, further exacerbating MR.¹¹² Thus chronic MR can both cause and be the result of LV remodeling and heart failure.

The causes of MR vary by geography, with mitral valve prolapse being the most common in industrialized nations. Rheumatic MR remains common in developing countries. The causes of acute MR include ischemic MR, endocarditis, chordal rupture, papillary muscle dysfunction, and a variety of diseases affecting prosthetic valves (Box 32.3). The most likely causes of acute MR in the critical care setting are ischemia, including acute myocardial infarction and infectious endocarditis, and should be considered in any patient who develops sudden hemodynamic decompensation in the peri-infarction period or who has known endocarditis. Chronic MR is secondary to a variety of structural, degenerative, connective tissue, inflammatory, and ischemic disorders, as well as congenital abnormalities outlined in Box 32.3.

The classic teaching has been that acute MR secondary to ischemia was caused by papillary muscle dysfunction, most likely secondary to ischemia of the posteromedial papillary muscle, which is dependent on a single blood supply from the right coronary artery. The anterolateral papillary muscle typically has dual circulation from the left anterior descending and circumflex coronary arteries, specifically from a diagonal branch and a circumflex marginal branch. The source of papillary muscle circulation is in fact variable, and on occasion the anterior papillary muscle also has a single blood supply.¹¹³ The role of impaired circulation to the papillary muscle as the cause of ischemic MR has been revisited,¹¹⁴ and evidence to date suggests that ischemic MR is secondary to alterations in ventricular geometry and leaflet tethering rather than dysfunction caused solely by impaired circulation to the papillary muscle during ischemia,¹¹⁵ although alterations in papillary muscle geometry can be seen in chronic ischemic MR.¹¹⁶ The hemodynamics of dynamic, ischemic MR are shown in Figure 32.12.

Box 32.3 Etiology of Acute and Chronic Mitral Insufficiency

Acute

Mitral Annular Disorders

Infective endocarditis (with abscess)
Trauma (e.g., valve surgery)
Paravalvular leak
Surgical—suture interruption
Infection

Mitral Leaflet Disorders

Infective endocarditis (with perforation or vegetation interfering with coaptation)
Trauma
Atrial myxoma
Myxomatous degeneration
Systemic lupus erythematosus (Libman-Sacks lesions)

Chordal Rupture

Spontaneous
Myxomatous degeneration
Mitral valve prolapse
Marfan syndrome
Ehlers-Danlos syndrome
Infective endocarditis
Acute rheumatic fever
Trauma

Papillary Muscle Disorders

Coronary artery disease
Acute global left ventricular dysfunction
Infiltrative diseases (amyloidosis, sarcoidosis)
Trauma

Primary Mitral Valve Prosthetic Disorders

Bioprosthetic cusp perforation
Bioprosthetic cusp degeneration
Mechanical failure (e.g., strut fracture)
Immobilized disk or ball

Chronic

Inflammatory

Rheumatic heart disease
Systemic lupus erythematosus
Scleroderma

Degenerative

Myxomatous degeneration (mitral valve prolapse)
Marfan syndrome
Ehlers-Danlos syndrome
Pseudoxanthoma elasticum
Calcification of mitral valve annulus

Infective

Endocarditis

Structural

Ruptured chordae tendineae
Spontaneous secondary to:
Myocardial infarction
Trauma
Mitral valve prolapse
Endocarditis
Rupture or dysfunction of papillary muscle (ischemia or infarction)
Dilation of mitral valve annulus and left ventricular cavity
Congestive cardiomyopathies
Aneurysmal dilation of the left ventricle
Hypertrophic cardiomyopathy
Paravalvular prosthetic leak

Congenital

Mitral valve clefts or fenestrations
Parachute mitral valve abnormality in association with other congenital disorders

From Otto C, Bonow RO: Valvular heart disease. In Libby P, Bonow RO, Mann DL, Zipes DP (eds): Braunwald's Heart Disease. A Textbook of Cardiovascular Medicine. Philadelphia, WB Saunders, 2008, p 1657.

Figure 32.12 Dynamic mitral insufficiency in a patient with transient left ventricular dysfunction after recent acute myocardial infarction. The panel on the left demonstrates hemodynamics on a 40 mm Hg scale at baseline (**A**). Note elevated filling pressures at a mean of 24 mm Hg with V waves at average height of 32 mm Hg. The panel on the right (**B**) shows tracings recorded a few minutes later. Mean pulmonary capillary wedge pressure rose to 33 mm Hg with V waves to 48 mm Hg. A, A wave; PCWP, pulmonary capillary wedge pressure; V, V wave.

Analysis of thrombolysis in myocardial infarction data showed a 27% incidence of MR most commonly in the setting of anterior rather than inferior myocardial infarction, although these values vary widely by criteria and techniques used for screening, with the incidence ranging from 11% to 59%.¹¹⁷ A Mayo Clinic review of more than 1300 acute myocardial infarction patients found moderate to severe MR in 12% and found it to be an independent predictor of both heart failure and survival.¹¹⁸ It is associated with multivessel coronary artery disease, as well as prior infarction.¹¹⁹

Papillary muscle rupture is a rare but potentially catastrophic cause of flail leaflets and represents a surgical emergency.¹²⁰ In addition to the typical acute myocardial infarction setting, it may be secondary to trauma and isolated other causes such as postpartum Ehlers-Danlos syndrome.¹²¹ Other causes of acute MR to consider (see [Box 32.3](#)) include spontaneous chordal rupture, infectious endocarditis with distortion of the valve leaflets or chordal rupture, and prosthetic valve dysfunction including paravalvular prosthetic valve leak. In patients with sudden onset of acute MR, retrograde flow is typically into a normal-sized and relatively noncompliant left atrium unless preexisting atrial hypertension has been present. The sudden volume loading immediately places the left atrium on the steep portion of its pressure-volume curve, which commonly causes acute pulmonary edema. As is the case with acute AI, the left ventricle is unable to adapt acutely and effective forward stroke volume is decreased. In the setting of myocardial infarction in particular, patients with acute MR may develop cardiogenic shock.

The classic hemodynamic response, a giant V wave, is shown in [Figure 32.13](#). Differentiating a giant V wave from a prominent pulmonary artery pressure waveform can be difficult in the critical care setting, and repeated attempts to obtain a wedge pressure when the catheter is already in the wedge position may result in iatrogenic pulmonary artery hemorrhage.

DIAGNOSIS

PHYSICAL EXAMINATION

In acute MR the abrupt rise of left atrial pressure results from torrential retrograde flow, although the gradient between the left atrium and left ventricle may narrow substantially near the end of systole because of the substantial rise in left atrial pressure as shown in [Figure 32.13](#). Thus the systolic murmur may decrease in intensity prior to the onset of the aortic second heart sound. A systolic thrill may be noted. The sudden and severe left atrial hypertension typically results in pulmonary edema with accompanying physical findings, as well as an increase in the pulmonic second sound and paradoxical splitting of the second heart sound. Because the adaptive mechanisms are not yet in place, features of LV volume overload are not seen, although a prominent precordial impulse, reflecting increased (albeit retrograde) ejection, may be noted. Unlike AI, the pulse pressure is not increased and may be reduced to reflect the lower forward stroke volume.

In chronic MR, precordial features of volume overload include a displaced point of maximal impulse and prominent precordial pulsation. An S_3 gallop is heard, especially

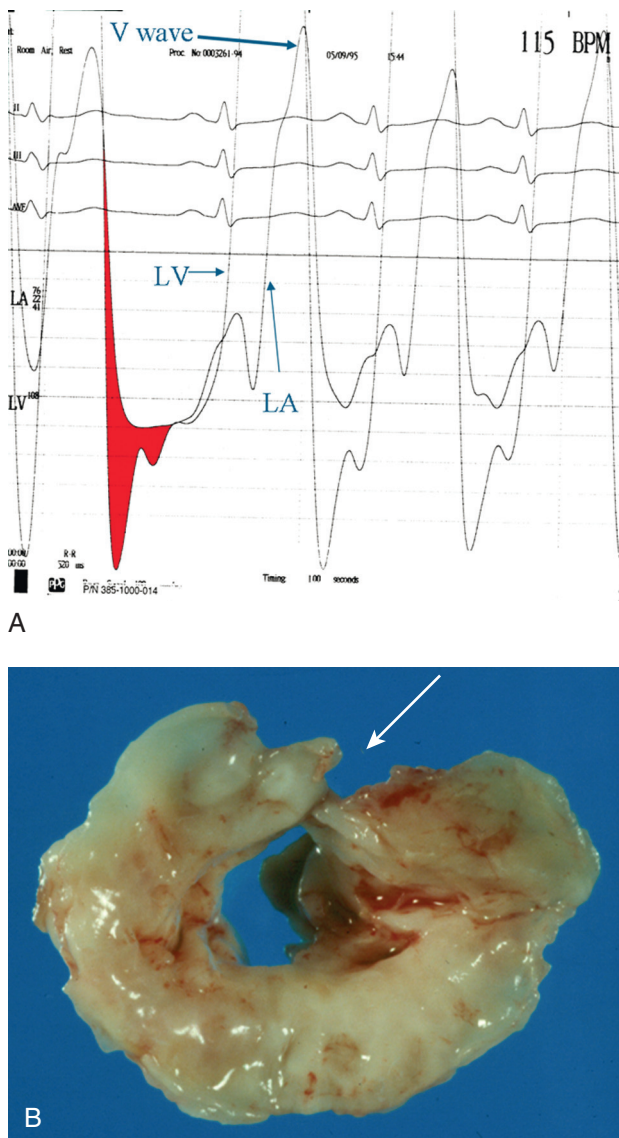

Figure 32.13 Hemodynamics (A) of severe MR (40 mm Hg scale) with giant V wave (to 70 mm Hg) late in systole. As LA pressure rises in acute severe mitral regurgitation, the gradient between the LV and LA pressure tracing is reduced and may result in a decrease in intensity of the murmur in late systole. The markedly thickened mitral valve (B) was excised from this patient after being torn (arrow) during balloon mitral commissurotomy. Elimination of mitral stenosis gradient (area in A, filled in red) is demonstrated. LA, left atrium; LV, left ventricle; MR, mitral valve insufficiency.

with marked dilation of the left ventricle,⁸⁸ and a diastolic flow murmur representing increased transvalvular flow (rather than mitral stenosis) may be present. The first heart sound may be soft, reflecting lack of brisk apposition of the mitral valve leaflets. The murmur of MR commences immediately following the first heart sound, reflecting the observation that a significant amount of regurgitation takes place during what would otherwise be isovolumic systole (which normally commences immediately following mitral valve closure). The murmur of chronic MR is characteristically blowing; may be medium or high pitched; is best heard at the apex; radiates to the axilla and left scapula (when severe); and extends

throughout systole, reflecting the presence of a relatively high gradient throughout LV ejection.

The location of radiation can provide a clue to the affected leaflet: anteriorly directed jets result from posterior leaflet dysfunction, and conversely anterior leaflet prolapse results in a murmur best heard toward the patient's back. Because the Gallavardin phenomenon in AS mimics an MR murmur, it is important to differentiate these two when possible (AS and MR frequently occur concurrently, given the high LV systolic pressure with the former). The murmur of MR differs because it is holosystolic and increases rather than decreases with handgrip.

The intensity of the MR murmur reflects a number of phenomena relating to the size of the gradient, compliance of the left ventricle and left atrium, and contractility of the left ventricle but does not correlate well with extent of MR; thus, the murmur may be difficult to hear or inaudible, especially in the critical care setting.¹²²

NONINVASIVE EVALUATION

Echocardiography provides visualization of the multiple structures responsible for causing MR including the valve leaflets, annulus, chordae tendineae papillary muscles, and left ventricle (see Fig. 32.11). Transesophageal echo provides superior imaging of the valve including assessment for vegetations in case endocarditis is suspected and better visualization of flail leaflets; it is particularly useful when the transthoracic views are incomplete or inadequate. In general, transesophageal echo is superior for fully assessing characteristics of the mitral regurgitant jet¹²³ and provides additional information in evaluating mitral valve morphology and motion. As with AI, Doppler methods allow assessment of the width of the regurgitant jet and size of the vena contracta, and semiquantitative measures of the regurgitant volume, regurgitant jet, and effective orifice area (see Table 32.1) are discussed in detail in Chapter 8. In patients presenting with acute heart failure and a hyperdynamic left ventricle, acute MR should always be considered.

CARDIAC CATHETERIZATION

Although the indications for cardiac catheterization (see Box 32.1) are similar to those for AS and AI, an additional consideration is included as a class I indication: to assess pulmonary artery pressures at rest and if necessary with exercise to evaluate appropriateness for surgery (see valve replacement indications later). The size of the V wave is not an accurate indicator of MR severity and is not used as a decision-making criterion for surgery because it may be unremarkable even in severe MR when there is high left atrial compliance. In addition, the size of the V wave is typically recorded by wedge rather than direct left atrial pressure, which can result in significant underestimation of the severity of MR (Fig. 32.14). Right heart catheterization and oxygen saturation sampling allow differentiation between the two most common causes of abrupt mechanical deterioration in acute MI: severe MR and ventricular septal defect. Both conditions can feature a large V wave because of sudden volume loading of a noncompliant left atrium: secondary to retrograde flow across the mitral valve in the case of acute MR and antegrade flow of shunted blood from the LV across the pulmonary circulation in the case of a ventricular septal defect.

Figure 32.14 Underestimation of the left atrial V wave by pulmonary wedge pressure recording in the setting of severe mitral insufficiency (mitral regurgitation [MR]). The tracings show simultaneous left atrial and pulmonary artery wedge pressures in a patient with chronic severe MR because of paravalvular leak (40 mm Hg scale). The V wave on the wedge tracings is approximately 28 mm Hg, but on direct left atrial pressure the measurement obtained by transseptal puncture is 44 mm Hg. The gradients between wedge pressure and left atrial pressure during systole (area filled in blue) and during diastole (area filled in red) represent artifact because of damping and phase delay of pressure waveforms reflected across the pulmonary vascular bed. The effect of this damping is gross underestimation of the severity of the V wave and overestimation of any gradient between the left atrium (LA) and left ventricle; these in turn result in underestimation of severity of MR and overestimation of the severity of mitral stenosis when pulmonary wedge pressures are used. The mean of the two pressures is exactly the same.

THERAPY

MEDICAL MANAGEMENT

For acute, severe, symptomatic MR, the primary medical therapy consists of aggressive vasodilation with nitroprusside. It provides improved aortic flow, diminishes MR, and decreases left-sided filling pressures. In the setting of acute MR with shock, nitroprusside alone is usually considered undesirable because of poor end-organ perfusion if further hypotension is caused by the drug. Intra-aortic balloon pumping is highly effective in this setting¹²⁴ (see Chapter 7) because it lowers aortic impedance, improves cardiac output, and decreases regurgitant fraction at the same time as it restores blood pressure. A combination of an inotrope (typically dobutamine; a vasoconstrictor should be avoided) and nitroprusside can have similar salutary effects. When the acute MR is dynamic (i.e., occurs and resolves abruptly), the cause is frequently acute ischemia, and consideration should be given to evaluating the coronary circulation. In a small number of cases, acute coronary intervention has been documented to alleviate MR in the setting of acute ischemia.¹²⁵

Therapy for chronic MR is more controversial. Because afterload is typically not increased, the benefits of afterload reduction are without clear physiologic foundation. As such, ACE inhibitors have consistently been shown not to be effective for chronic MR.¹²⁶⁻¹²⁸ When concomitant systemic

hypertension exists, physiologic benefits appear more convincing.¹²⁹ If patients have LV dysfunction superimposed on chronic MR, medical therapy with ACE inhibitors may be beneficial, and several studies have observed functional improvement with resynchronization in this setting.¹³⁰ As with other valvular disorders, new-onset AF can result in abrupt hemodynamic deterioration and cardioversion should be considered with adjunctive pharmacotherapy to maintain sinus rhythm and rate control. Because of the sympathetic activation previously discussed, beta blockers appear to be beneficial^{131,132} and may have additive benefit when used in combination with ACE inhibitors.¹³³ Both classes of drugs appear to be therapeutic when used after mitral valve repair.¹³⁴

MITRAL VALVE SURGERY

Three types of surgeries are performed on the mitral valve: repair, replacement with preservation of the subvalvular apparatus and attachments, and replacement with transection of the chordae. Mitral valve repair has been consistently shown to improve outcomes compared with mitral valve replacement, both acutely and long term, with a fourfold lower operative mortality rate and a 30% improvement in 10-year survival rate.¹³⁵ With mitral valve replacement, patients who nevertheless have the chordal apparatus preserved have superior long-term outcomes compared with those who have the chords transected.¹³⁶ An additional benefit of repair is the avoidance of anticoagulation if patients are in sinus rhythm compared with replacement with a mechanical valve when anticoagulation is required.

In general, the timing of surgery for chronic MR should be prior to the onset of LV dysfunction. The most commonly used markers are symptoms and echocardiographic parameters including LVEF less than 60%.⁵ Patients who develop class III or IV symptoms, even transiently, have a nearly 10-fold increase in annual mortality rate,¹³⁷ with evidence that early surgery in the setting of severe MR improves overall survival. The 60% threshold for surgery has been shown to correlate with postoperative LV function¹³⁸ as well as survival.¹³⁹ More recently the effective regurgitant orifice has been shown to be strongly predictive of 5-year mortality risk, with patients having an orifice of 40 mm² or greater having an odds ratio of death greater than 5:1 compared with patients with orifice size of 20 mm² or less.¹⁴⁰ Preoperative end-systolic diameter of 40 mm or less has also been associated with superior outcomes. Patients with AF in general have a worse prognosis,¹⁴¹ although in large part because of embolic events rather than LV dysfunction, as do patients with pulmonary hypertension or right-sided heart failure, or both.¹⁴² Mitral valve surgery, even in the setting of depressed EF, may result in postoperative return to normal function.¹⁴³ Comparison of long-term outcomes between operated and medically treated patients with asymptomatic MR has invariably favored the former,¹⁴⁰ although much of the data depend on nonrandomized registry data. In general, the key to improved function and outcomes is preserving the integrity of the submitral apparatus,¹⁴⁴ and comparison of successful repair versus replacement has indicated that high-volume institutions (>140 mitral operations/year) have the best results with nearly twice the rate of successful repair as low-volume institutions.¹⁴⁵

A common teaching has been that repair or replacement of the mitral valve eliminates the “pop-off valve” represented by incompetent leaflets, resulting in dramatically increased afterload postoperatively. In turn, if significant preoperative LV dysfunction were present, the left ventricle would fail, with hemodynamic deterioration and subsequent death. In fact, careful investigation has demonstrated that postoperative deterioration of LV function was secondary to disruption of chordal integrity¹⁴⁶ and elimination of the favorable effects of the submitral apparatus on valvular-ventricular interaction rather than the elimination of a low-pressure decompression pathway. Afterload following mitral valve surgery with chordal transection does in fact increase, whereas patients subjected to mitral valve surgery with preservation of the chordal apparatus had decreased LV chamber volume and, in keeping with the LaPlace equation, reduced afterload.¹⁴⁷ Thus the recommendations regarding LVEF for surgery have changed dramatically, and successful repair of mitral valves in series of patients with EF less than 25% has been reported with operative risk of less than or equal to 5%.¹⁴⁸ The operative risk is in the 1% to 2% range for symptomatic patients with LV dysfunction but higher EF.¹⁴⁹ Similarly, the Society of Thoracic Surgeons database has reported mortality rates of approximately 5% with EF less than or equal to 30% but 3% with EF greater than 30%.¹⁵⁰ Propensity analysis of patients eligible for mitral valve repair who did or did not undergo the procedure has not shown a survival advantage in patients with mean EF less than 25%,¹³⁴ although a randomized trial has not been reported. Similarly, concomitant mitral valve surgery in patients undergoing coronary artery bypass graft (CABG) with moderate or greater MR did not clearly improve short-term survival.¹⁵¹ Combining mitral valve surgery with a mesh placed around the heart to help prevent dilation and thus lower wall stress may have additional benefit for patients with MR and LV dysfunction.¹⁴⁹ Only in the setting of an EF of less than 30% or end-systolic dimension greater than 55 mm, as well as anatomy or surgical experience that suggests chordal preservation is unlikely, do the current guidelines recommend medical therapy alone.

In symptomatic acute severe MR, mitral valve surgery is a class I indication regardless of level of LV function. Both with infective endocarditis,¹⁰⁴ as well as with papillary muscle rupture, surgery is mandated to be performed with as little delay as possible.¹⁵² However, the overall risk of mortality when MR accompanies acute myocardial infarction is substantially increased,¹⁵³ a phenomenon noted in patients undergoing emergent percutaneous intervention as well.¹⁵⁴ Chronic severe MR is much more complex, and the management algorithm is outlined in [Figure 32.15](#).

FUTURE DIRECTIONS

A number of innovative technologies are being developed for percutaneous treatment of MR. The most extensively studied is based on a catheter-based edge-to-edge repair of the mitral leaflets designed to mimic a surgical procedure developed by Alfieri and colleagues.¹⁵⁵ The EVEREST (Endovascular Valve Edge-to-edge REpair STudy) II trial¹⁵⁶ compared 184 patients randomized to percutaneous versus 95 patients randomized to surgical mitral valve repair and had promising though somewhat nuanced results: although there was good safety profile and similar quality of life

improvement, grade 2 or greater mitral insufficiency was present in nearly half the percutaneous repair patients at 1 year, compared with only 17% of the surgical repair patients. The surgical patients did have more adverse events, primarily blood transfusions. The surgical approach appeared clearly superior for patients with degenerative MR, with relative parity in outcomes in functional MR patients (those with structurally normal mitral valves, but typically dilatation of the mitral annulus). The Alfieri procedure is an uncommonly performed type of mitral valve repair, and as with most repair procedures typically involves placement of a prosthetic ring, an option not available with the percutaneous approach, and potentially a limitation of its long-term applicability as an isolated intervention.¹⁵⁷ In this context, it is worth noting that several percutaneous technologies are under development to constrict the coronary sinus that at least partially surrounds the mitral valve¹⁵⁸; they thereby attempt to mimic the mechanical effects of a surgically placed mitral ring. For now, percutaneous edge-to-edge repair has had fair acceptance outside the United States and is being performed primarily in the setting of functional MR. A number of other technologies are under development.

HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY

Although a disease of the heart muscle rather than a primary valvular disorder, hypertrophic obstructive cardiomyopathy (HOCM) has important features of LV outflow obstruction and concomitant MR. The clinical presentation, physical examination, noninvasive and invasive findings, and overall management differ in general from AS or MR, and HOCM represents an important consideration for patients in critical care units,¹⁵⁹ where patients with a systolic murmur and hypotension, syncope, or exercise-induced cardiac arrest in particular should have HOCM included in the differential diagnosis.

PATHOPHYSIOLOGY

The hallmark of HOCM is dynamic obstruction of the LV outflow tract with eccentric hypertrophy; many variations exist, and obstruction is not always at the subvalvular level. Only approximately one fourth to one third of patients with hypertrophic cardiomyopathy (HCM) have a resting gradient of 30 mm Hg or greater.¹⁶⁰ HCM is found in approximately 0.2% of the population¹⁶¹ and is defined as hypertrophy of the left ventricle that is not secondary to hypertrophic stimuli such as systemic hypertension or AS. Contrary to conventional wisdom, the majority of patients with HCM were found to have provokable gradients with exercise in a single large-volume center¹⁶² (likely with some skewing from the nature of its referral population). The genetics of HCM have been studied extensively, and although complex, there is a familial association in a majority of patients. Although the clinical course may be generally benign in patients without risk factors for adverse events,¹⁶³ it is the most common cardiac cause of sudden death in young adults,¹⁶⁴ is associated with cardiac arrest in athletes,¹⁶⁵ and leads to heart failure, rhythm disturbances, and

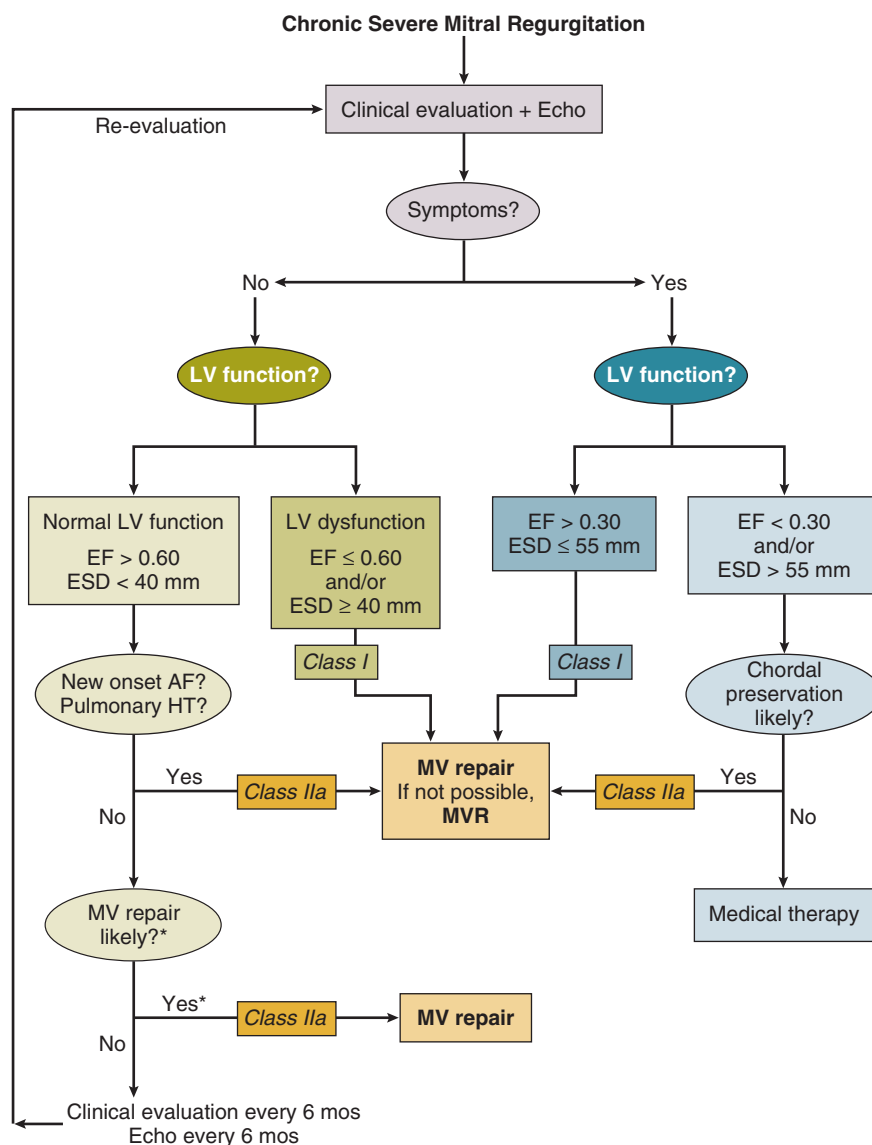

Figure 32.15 Algorithm for management of patients with chronic severe mitral regurgitation. *Mitral valve repair may be performed in asymptomatic patients with normal left ventricular (LV) function if performed by an experienced surgical team and if the likelihood of successful mitral valve (MV) repair is greater than 90%. AF, atrial fibrillation; EF, ejection fraction; ESD, end-systolic dimension; HT, hypertension; MVR, mitral valve replacement. (From Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease] developed in collaboration with the Society of Cardiovascular Anesthesiologists and endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. *J Am Coll Cardiol* 2006;48:e1-148.)

occasional sudden death in older patients. The patients at high risk for sudden death, composing only about 10% to 20% of those within the HCM population, include those with prior cardiac arrest or sustained ventricular tachycardia, those with a family history of HCM and sudden death, hypotensive response to exercise, and severe LVH with wall thickness of 30 mm or greater.¹⁶⁶ A resting gradient across the outflow tract of more than 30 mm Hg alone predicts an increased risk of sudden death or development of moderate to severe congestive heart failure,¹⁶⁰ and there may be higher risk with very high gradients.¹⁶⁷ Because of impaired coronary flow reserve¹⁶⁸ and severe hypertrophy, myocardial ischemia is a potentially important factor in acute patient

management; there is also an association between HOCM and myocardial coronary bridging.¹⁶⁹

DIAGNOSIS

PHYSICAL EXAMINATION

The physical examination in HOCM features an abrupt early rise in systolic pressure followed by obstruction to LV outflow, resulting in a blunted pressure rise later in systole. This translates to the spike and dome pattern characteristic of HOCM on palpation of the carotid pulse. The typically hypertrophic septum (1.3 to 1.5 times the thickness of the posterior wall and typically 18 mm or greater in clinically

significant HOCM) obstructs the outflow tract after initial ejection as LV volume decreases. Physiologic maneuvers or clinical states that lower LV volume abruptly such as standing, dehydration, or use of diuretics can substantially exacerbate the gradient and increase the intensity of the systolic ejection murmur characteristic of HOCM. Because the obstruction begins after the initial brisk ejection of blood from the ventricle, the onset of murmur is late after the first heart sound. It is best heard over the left base of the heart. In contrast to AS, the murmur typically does not radiate to the carotids, does not extend throughout systole, and decreases with squatting. The blunting of the carotid upstroke, so characteristic of AS, is not seen because of the vigorous early ejection.

NONINVASIVE EVALUATION

Abnormalities of mitral valve function are common. Systolic anterior motion of the mitral valve is associated with further obstruction¹⁷⁰; in addition, MR is a typical secondary finding in HOCM. The ECG features LV hypertrophy, strain, and prominent Q waves in the inferior and precordial leads, with narrow QRS complexes being common. The echocardiogram is diagnostic for HOCM, providing both an anatomic basis and physiologic evidence of the degree of obstruction (Fig. 32.16).

CARDIAC CATHETERIZATION

Cardiac catheterization in HOCM may reveal the standard triad of the Brockenbrough-Braunwald-Morrow sign in the postextrasystolic heartbeat: increase in the gradient between the left ventricle and the aorta, decrease in systemic blood pressure, and narrowing of the pulse pressure (Fig. 32.17). Other stimuli that increase outflow obstruction and increase gradient are Valsalva maneuver and amyl nitrite inhalation, in addition to postextrasystolic potentiation.

THERAPY

MEDICAL MANAGEMENT

The management of critically ill patients with HOCM focuses on several core principles: optimizing LV volumes, specifically increasing preload while not decreasing afterload, decreasing contractility, and maintaining the patient in sinus rhythm. Thus the typical regimen of diuretics, vasodilators, and inotropes used in most patients presenting with congestive heart failure who do not have HOCM can severely exacerbate the outflow gradient and lead to further decompensation or death¹⁷¹ (as can intra-aortic balloon pumping); somewhat counterintuitively in this setting, negative inotropes, in particular beta blockers, combined with volume loading can stabilize patients.^{172,173} Other negative inotropes including verapamil and disopyramide appear to have favorable hemodynamic effects and may represent an alternative to beta blockade.¹⁷⁴ In the patient in shock, if vasopressors are required, agents such as phenylephrine, which are primarily peripheral vasoconstrictors, should be used rather than inotropic agents. Verapamil has negative inotropic benefits and some utility as an antiarrhythmic agent, as well as diastolic relaxation properties, and has been used successfully in both chronic therapy and acutely decompensated patients with HOCM.¹⁷⁵ Verapamil does have some potentially undesirable vasodilator properties

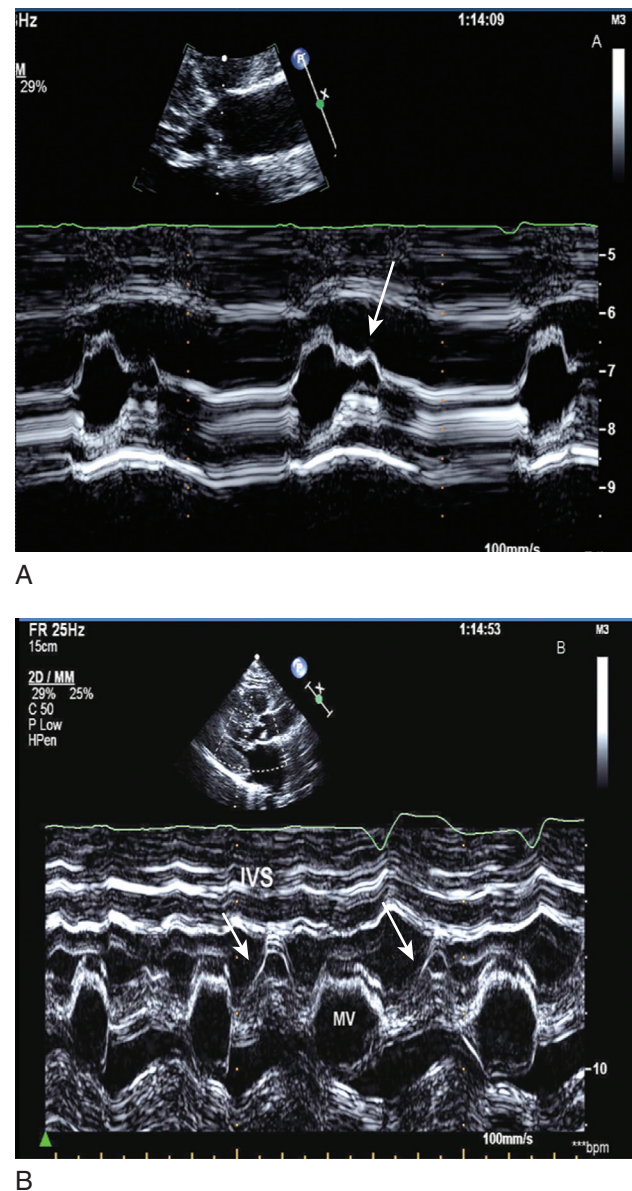

Figure 32.16 A, M-mode of hypertrophic obstructive cardiomyopathy with aortic valve opening showing the effect of midsystolic outflow obstruction; after initial normal opening, the aortic valve leaflets remain only partially separated because of diminished transvalvular flow (arrow). B, Systolic anterior motion of the anterior mitral leaflet with apposition against outflow tract (arrows). The severely hypertrophied septum on two-dimensional view is shown at the top of each panel.

and can cause synergistic depression of conduction and contractility in combination with beta blockade; the effects of combined therapy, if used, should be monitored closely.¹⁷⁶

Patients with hypertrophic heart disease are highly dependent on the atrial contribution to cardiac output,¹⁷⁷ and patients with obstruction in particular depend on the additional LV filling from atrial contraction. AF is a cause of acute decompensation in HOCM patients, and cardioversion should be considered acutely. AF occurred in approximately one fourth of patients with HCM followed for 9 years and is predictive of heart failure–related death and stroke.¹⁷⁸ In terms of the latter, patients with HCM and

Figure 32.17 The Brockenbrough-Braunwald-Morrow sign. Dramatic exaggeration of the resting gradient in the postextrasystolic beat, with lower systemic pressure, and narrowed pulse pressure (difference between femoral systolic and diastolic pressure) are demonstrated—all hallmarks of dynamic outflow obstruction. *Dashed lines* represent left ventricle (LV) and aortic systolic pressures at rest (*green*) and after a premature ventricular contraction (PVC) (*red*); the gradient rises from a basal 30 mm Hg (*double-sided green arrow*) to approximately 130 mm Hg (*double-sided red arrow*). (Modified from Pollock SG: Pressure tracings in obstructive cardiomyopathy. *N Engl J Med* 1994;331:238.)

AF appear particularly predisposed to thromboembolic events¹⁷⁹; anticoagulation has been shown to reduce the incidence significantly.¹⁸⁰ Left atrial size and function predict the onset of AF.¹⁸¹ The Maze procedure and catheter ablation of left atrial pathways have been used successfully in small series to prevent recurrent AF.^{182,183} Amiodarone has been particularly effective for the maintenance of sinus rhythm in the population with AF and HCM¹⁸⁴ and may also have additional efficacy in preventing sudden death in patients with episodes of nonsustained ventricular tachycardia.^{185,186} Ventricular fibrillation appears to be the primary cause of sudden death and can be prevented with implantable defibrillators for either primary or secondary prevention, with activation of the devices in 5% to 11% of patients annually depending on indications for placement¹⁸⁷; episodes of sustained ventricular tachycardia and a history of prior sudden death place patients in the highest risk category.

PERCUTANEOUS INTERVENTION OR SURGERY

Once patients develop refractory symptoms despite pharmacologic management and have significant obstruction to LV outflow, surgical myomectomy or alcohol septal ablation must be considered. The choice is controversial and depends on LV and coronary anatomy, comorbid conditions, severity of coexistent mitral valve or other potentially surgical heart disease, and a variety of other clinical issues; equivalence of outcomes with the less invasive percutaneous approach has not been demonstrated.¹⁸⁸ Typical thresholds for intervention are a resting peak instantaneous gradient of 50 mm Hg

or more, although depending on degree of symptoms and provokability, a variety of other thresholds have been applied.¹⁶⁶ Mitral valve replacement can frequently be avoided, especially in patients without intrinsic mitral disease, in whom MR is largely abolished by myomectomy and relief of the outflow gradient.¹⁸⁹ In patients with intrinsic mitral valve disease or for a variety of other anatomic considerations, mitral valve surgery including use of low-profile prostheses is used.¹⁶⁶ Dual-chamber pacing, once considered therapeutically effective,¹⁹⁰ with theoretical benefit from asynchronous septal contraction and secondary reduction in outflow tract gradient, has not been shown to have clear therapeutic benefit in randomized clinical trials, with the most likely functional benefits occurring in a limited subset of elderly patients.¹⁹¹

MITRAL VALVE STENOSIS

Mitral valve stenosis (MS) is primarily a rheumatic disorder and, as such, has become increasingly uncommon in industrialized nations. Nevertheless, the disease remains prevalent in developing countries and a small but significant number of patients continue to present in the critical care setting throughout the world. Rheumatic MS involves disease of both the valve leaflets and submitral apparatus and may involve the valve ring as well (Fig. 32.18). Although MS is primarily caused by rheumatic deformity and scarring of the valve leaflets and subvalve with fusion of the

Figure 32.18 Long-axis view during diastole of the mitral apparatus, left atrium, and left ventricle in a normal patient (**A**) and a patient with mitral stenosis (**B**). Cross-sectional views of the left atrial surface of the valve are shown in the inset. With mitral stenosis, the valve opening is restricted with a characteristic doming appearance, the commissures are fused, the leaflets are thickened, the subvalvular apparatus is deformed, and some calcification is noted. The left atrium is enlarged. (From Turi ZG: Cardiology patient page. Mitral valve disease. *Circulation* 2004;109:e38-e41.)

commissures, a variety of disorders result in leaflet and annular calcification that also create obstruction between the left atrium and left ventricle. Most notably, mitral annular calcification, present in 6% of patients undergoing routine echocardiography,¹⁹² is more prevalent in the elderly, women, smokers, and patients on dialysis (who have high parathyroid hormone levels). It may present with severe nonrheumatic mitral stenosis, although MR is a more common association.^{192,193} A variety of uncommon other causes account for less than 1% of cases of MS.¹⁹⁴

PATHOPHYSIOLOGY

The physiologic hallmark of MS is obstruction to left atrial outflow resulting in rising left atrial and pulmonary pressures (the extent of the latter depends to a significant degree on left atrial compliance). The normal mitral valve is in the range of 4 to 6 cm², and patients typically do not become symptomatic until valve areas decrease significantly below 2 cm² (see [Table 32.1](#)). As valve area decreases, an additional pressure gradient is required to maintain transvalvular flow (see [Fig. 32.5](#)). Because antegrade flow is entirely during diastole, and the diastolic filling period shortens or lengthens disproportionately with increase or decrease in heart rate, respectively, the gradient is highly flow dependent. In MS, as with virtually all valvulopathies, cardiac output is potentially highly dependent on maintenance of sinus rhythm; because the influence on cardiac output is exaggerated by the need for active left atrial pumping across a stenotic orifice, atrial contraction is particularly important in MS. A frequent mode of presentation is acute congestive heart failure in a patient with MS who suddenly develops AF; the concomitant loss of atrial contraction and high ventricular rate with short diastolic filling period frequently results in pulmonary edema.

DIAGNOSIS

PHYSICAL EXAMINATION

The diagnosis of MS on physical examination is frequently missed, in part because it is uncommonly seen by most practitioners outside developing countries. Besides findings suggestive of congestive heart failure with a low output in the critical care setting, several findings correlate strongly with MS. A right ventricular lift may occur in patients with advanced and chronic pulmonary hypertension, and occasionally a palpable pulmonary second sound is felt. Both S₁ and P₂ are increased early in the course of the disease; with progressive deformity of the subvalvular apparatus, S₁ may become quite soft as mitral valve closure velocity decreases. The opening snap is preserved until the end stages of MS, and the severity of the disease correlates inversely with the length of time between S₂ and the opening snap. The diastolic rumble may not be heard if the patient is not placed in the lateral decubitus position and is difficult to hear in the critical care setting. Presystolic accentuation is the result of increased flow in late diastole caused by atrial contraction in patients in sinus rhythm. The diagnosis is often missed in both the outpatient and critical care settings,¹⁹⁵ and patients are sometimes treated for years for bronchitis, pneumonia, or asthma, when in fact the presentation is congestive heart failure with the underlying disease process being MS.

NONINVASIVE EVALUATION

The echocardiogram is the primary tool for diagnosis of MS. The typical hockey stick appearance of the rheumatic anterior mitral leaflet is caused by partial restriction of mobility (Fig. 32.19). Other important characteristics of the mitral leaflets are degree of thickening, mobility, and calcification, all of which, along with extent of subvalvular disease, help to address suitability for balloon dilation or commissurotomy rather than valve replacement.¹⁹⁶ It is important to differentiate rheumatic MS from severe nonrheumatic MS, as shown in Figure 32.19. Transesophageal echo provides the requisite sensitivity to detect left atrial thrombus prior to balloon commissurotomy or cardioversion. Severity of mitral stenosis is graded by physiologic and anatomic criteria: The former depend on Doppler interrogation of transvalvular flow, with peak velocity used to estimate the gradient; rate of decompression of the left atrial pressure, or pressure half time, correlates inversely with valve area. The valve area is frequently directly measured using planimetry of a cross-sectional view. Because these methods have potential for

Figure 32.19 Two appearances of stenotic mitral valves. **A**, The parasternal long axis view shows typical rheumatic deformity with a hockey stick appearance of the anterior mitral leaflet (arrow). **B**, The four-chamber view is from a patient with a significant gradient across the mitral orifice; this patient was on dialysis, did not have rheumatic heart disease, and demonstrated significant calcification of the mitral leaflets and annulus (arrow). LA, left atrium; LV, left ventricle.

error, a number of alternative methodologies have been proposed,¹⁹⁷⁻¹⁹⁹ although there is no agreement on a gold standard.²⁰⁰ As with AS, a dramatic increase in gradient accompanies increased flow related to exercise or dobutamine infusion²⁰¹ (Figs. 32.20 and 32.21). Cardiac catheterization may be required if the noninvasive data are inconclusive; there is a tendency for the pulmonary wedge pressure/LV gradient to overestimate the severity of MS compared with left atrial/LV gradient measurement²⁰² (Fig. 32.22). Cardiac catheterization can also be used to assess pulmonary artery pressures and response to exercise if the clinical and noninvasive pictures are discordant.⁵

THERAPY

MEDICAL THERAPY

Medical therapy specifically aimed at improving hemodynamics in MS is basically twofold: slowing the heart rate and anticoagulation. In sinus rhythm, beta blockade is the preferred therapy; patients with significant bronchospasm or with coexistent, usually secondary, severe pulmonary hypertension with or without right-sided heart failure may not tolerate beta blockers. Diltiazem or low doses of beta blocker combined with diltiazem or verapamil are sometimes used in this setting. With combined therapy, care should be exercised that severe heart rate slowing or atrioventricular block does not occur, and verapamil may not be tolerated in right-sided heart failure. For the acutely decompensated patient with MS, diuretics, nitrates, inotropes (preferably agents that do not raise heart rate), and, to a lesser degree, arterial vasodilator therapy may all be beneficial.

Approximately 30% of patients with MS are thought to develop AF, with the risk increased by progressive increase in left atrial size. The risk of embolic events, especially stroke, is substantially higher than in AF patients without MS²⁰³ (up to 15% in unanticoagulated patients), possibly in part because of a hypercoagulopathy and increased platelet activation associated with MS,²⁰⁴ making the use of anticoagulation essential. It is not uncommon for the presenting finding to be an embolic event in a previously undiagnosed MS patient. Even in the setting of sinus rhythm,⁵ if spontaneous echo contrast is seen in the MS patient or left atrial size is greater than 55 mm, anticoagulation may decrease stroke risk²⁰⁴ and it should also be used in the sinus rhythm patient with prior embolic event or with left atrial thrombus detected by transesophageal echocardiography.

In the setting of new-onset AF and acute decompensation, cardioversion should be considered. Regardless of chronicity, heart rate slowing is essential; digoxin, beta blockers, diltiazem, or verapamil alone or in combination may be beneficial. Rate control only at rest is inadequate; many patients with low resting heart rates become tachycardic with minimal exercise. This is a vicious circle because the tachycardia may be a response to inadequate stroke volume; the tachycardia then lowers the diastolic filling period and further exacerbates the gradient. Control of tachycardia is important beyond its hemodynamic benefit; it also helps avoid tachycardia-induced cardiomyopathy.²⁰⁵

PERCUTANEOUS INTERVENTION OR SURGERY

Percutaneous balloon mitral valvuloplasty is equivalent or superior to surgery in patients with favorable valve

Figure 32.20 Effect of exercise and increased heart rate on mitral valve gradient (red) in a patient with mitral valve stenosis (40 mm Hg scale). The left tracing (A) shows a mean gradient of approximately 5 mm Hg with diastasis late in diastole; with increased heart rate and cardiac output (B), the gradient rose to a mean of approximately 20 mm Hg, a fourfold increase. LV, left ventricle; PAW, pulmonary artery wedge.

Figure 32.21 Effect of dobutamine infusion on transmitral valve gradient (40 mm Hg scale). Effect in a patient whose gradient was nearly abolished at rest (A) and was augmented dramatically with infusion of dobutamine (B).

Figure 32.22 Effect of using pulmonary wedge pressure (A) or direct left atrial pressure (B) to assess gradient (in red) between the left atrium and left ventricle in mitral stenosis (40 mm Hg scale). Using the wedge pressure, the gradient appears to be approximately twice as great as when left atrial pressure is used. Rapid decompression of left atrial pressure is shown in the tracing on the right. The findings are consistent with mixed mitral stenosis and regurgitation, with the dominant physiology being secondary to mitral insufficiency. In both tracings, diastasis (D) is noted by end diastole, a feature not consistent with severe mitral stenosis except in marked bradycardia. The V wave height is similar in both tracings, unlike in Figure 32.12. The two tracings shown here were recorded a few seconds apart.

anatomy,^{206,207} characterized by mild to moderate impairment of leaflet mobility, valve thickness, valve calcification, and subvalvular disease, the components of the Wilkins-Weyman echo score.²⁰⁸ The scoring system has been shown to correlate with long-term outcomes.²⁰⁹ Surgery should be reserved for patients with unfavorable anatomy, more than mild MR, or persistent thrombus in the left atrium despite anticoagulation.⁵ The threshold for percutaneous or surgical intervention is a mitral valve area of 1.5 cm² or less. If patients are symptomatic and have favorable anatomy or if they are asymptomatic but have pulmonary hypertension (>50 mm Hg systolic at rest or >60 mm Hg with exercise), they have class I indications. Patients who have unfavorable anatomy and are functional class III or IV are considered to have a class II indication, especially if they are poor candidates for surgery. Asymptomatic patients with new-onset AF and favorable anatomy and symptomatic patients with mild MS (valve area >1.5 cm²) who have pulmonary artery pressure greater than 60 mm Hg, wedge pressure 25 mm Hg or greater, or gradient 15 mm Hg or greater during exercise are also considered class II candidates.⁵

KEY POINTS

- Valvular heart disease in the critical care setting ranges from the primary cause of acute decompensation to a comorbid condition of varying degrees of clinical significance.
- Valvulopathy affects not only valve anatomy but also cardiac structure and function and overall hemodynamics; it is essential to consider all four elements in diagnosis and management.
- AS in the critical care setting requires careful titration of need to maintain cardiac output, avoid hypotension, and replace the aortic valve early if AS is the primary cause of symptoms.
- Low-gradient, low-output AS requires increasing cardiac contractility or transvalvular flow, or both, to differentiate severe AS from primary myocardial dysfunction.
- Acute aortic and mitral insufficiency in the decompensated patient benefits from vasodilator

KEY POINTS (Continued)

therapy; vasodilator treatment of chronic aortic and mitral insufficiency in asymptomatic patients does not have the benefit of a compelling evidence base.

- Intra-aortic balloon counterpulsation is useful in hemodynamically decompensated MR patients, is of some benefit in severely ill AS patients, but is contraindicated with HOCM and particularly in patients with AI.
- AF exacerbates hemodynamic deterioration in valvulopathies; if left atrial size is less than 6 cm and thrombus is not present, cardioversion and maintenance of sinus rhythm are highly beneficial.
- There are now only limited indications for prophylactic therapy with antibiotics for endocarditis prevention for the valvulopathies described in this chapter,²¹⁰ primarily the presence of prosthetic cardiac valves and a history of previous infectious endocarditis.

ACKNOWLEDGMENT

The author wishes to acknowledge Priscilla Peters for kindly providing [Figures 32.10, 32.16, and 32.19](#).

SUMMARY

INTRODUCTION

Thoracic aortic dissection (TAD) occurs with communication between the thoracic aorta lumen and wall with a separation of the thoracic aortic wall layers. Thoracic aortic dissection is to be contrasted with thoracic aortic aneurysm (TAA), which is defined as dilation of the thoracic aorta to a diameter of ≥ 1.5 times normal. Thoracic aortic aneurysm is a risk factor for TAD. Thoracic aortic aneurysm, although an important morbidity that may be associated with acute catastrophic leakage and death, is in and of itself not the acute emergency that is signified by a TAD. The international registry of acute aortic dissection reported an overall mortality of 27.4% with this condition. Surgical mortality was 26% for proximal (type A dissection) versus 58% for medical management and for distal (type B dissection), with 10.7% for medical management and 31% for surgical management.¹

HISTORY

In 1819, Laenec introduced “aortic dissection” into the medical literature when he described an intimal tear distal to the aortic valve associated with a longitudinal space in the aortic wall postmortem.² An autopsy report in 1760 described aortic dissection and pericardial tamponade as the causes of death of King George II.³ In 1863, Peacock reported a summary of findings in 80 patients with aortic dissection and classified the disease into three stages: intimal tear, propagation of the dissection with the potential for rupture, and recanalization of the lumen.⁴ In 1896, Marfan described

the aortic connective tissue abnormality now known to be associated with this entity.⁵ In 1955, DeBakey treated a descending thoracic aortic dissection with resection and reapproximation of dissected layers with graft interposition.⁶ In 1963, DeBakey and colleagues repaired an ascending aortic dissection complicated by aortic valvular insufficiency.⁷

TYPES OF TAD

The thoracic aorta is divided anatomically into the ascending portion, the transverse portion, and the descending portion.⁸ The ascending aorta has two sections, the aortic root (valvular annulus and sinuses) and the tubular portion extending to the origin of the innominate artery. The transverse portion of the aorta is a short segment, and the brachiocephalic arteries come off this portion of the aorta. The descending thoracic aorta begins immediately distal to the left subclavian artery and extends to the diaphragm. The anatomic location of TAD has important clinical and prognostic implications. The most commonly used classification scheme for TAD is the Stanford System (Fig. 33.1), which has mostly replaced the first classification system, the DeBakey System (see Fig. 33.1). An advantage of the DeBakey System is that it does distinguish between dissections that are confined only to the ascending aorta (DeBakey type 2) and dissections that involve the entire aorta (DeBakey type 1). Using the Stanford System, which is more simplistic, any involvement of the ascending aorta classifies the dissection as a Stanford A, whereas lack of ascending aorta involvement classifies the dissection as a Stanford type B.

Figure 33.1 Pictorial representation of DeBakey 1, 2, and 3 as well as Stanford A and B classification of thoracic aortic aneurysms. (Used with permission. Braunwald E: Heart Disease: Textbook of Cardiovascular Medicine, 9th ed. Boston, WB Saunders.)

RISK FACTORS FOR THORACIC AORTIC DISSECTION

Multiple risk factors for TAD have been identified.⁸ Men are at greater risk for developing TAD than women; approximately two thirds of patients with TAD are male.⁹ The sex distribution is consistent across different classifications of aortic dissection. Women with TAD are more likely than men to have a history of hypertension. Women are older at the time of diagnosis of TAD when compared to men. The average age at diagnosis of TAD is 65 years and is younger for type A TAD than for type B TAD.⁸ Specific risk factors for TAD are shown in [Table 33.1](#). It is thought that the higher the blood pressure, the greater the probability of aortic dissection. In the presence of coarctation of the aorta, acute dissection typically occurs proximally rather than distal to the coarctation. The majority of patients with aortic dissection have hypertensive disease at the time of diagnosis.¹⁰ It is thought that blood pressure control decreases the occurrence of aortic dissection. However, hypertension is not thought to be the sole cause of dissection in a given patient. Many think that pregnancy is an independent risk factor for aortic dissection, although analysis of the available data and the conclusions from these data is hampered by the small number of patients affected and coexisting additional predisposing factors such as hypertension.¹¹⁻¹³ In addition to blunt trauma, thoracic aortic dissection may be induced following establishing antegrade or retrograde arterial perfusion during cardiopulmonary bypass. Intra-aortic balloon counter-pulsation use may also trigger aortic dissection. There is increased risk of type A TAD after aortic valve replacement, especially with larger aortic diameters.¹⁴ Finally, diagnostic angiography and cardiac catheterization may be complicated by aortic dissection (see [Table 33.1](#)).¹⁴

PATHOPHYSIOLOGY

The aortic wall is composed of three layers: the innermost intima, the media (smooth muscle and elastic connective tissue), and the outermost adventitia. Hemodynamic stresses to the aortic inner walls can result from risk factors such as prolonged hypertension or inherently weakened connective tissue walls as seen in some connective tissue syndromes or a bicuspid aortic valve that alters the flow pattern of blood ejected out of the aorta. A dissection may be initiated by a tear or ulceration of the medial layer facilitated by degeneration from normal aging or compounded by the risk factors listed in [Table 33.1](#). A classic aortic dissection is classified by an intimal tear into the media of the aortic wall, resulting in separation of the medial layer and formation of a false channel, allowing blood to flow into this channel. An intramural hematoma (IMH) can also be the trigger for a dissection when an accumulation of blood separates the medial layers; in this circumstance, the inciting entrance tear is lacking. IMH is more common in the elderly hypertensive patient's descending aorta. Finally, aortic ulcers can disrupt the aortic wall and result in aortic rupture or dissection. Patients with aortic ulcers are older than those with IMH. The false lumen of a TAD has the potential to extend both distally and proximally, potentially leading to obstruction of arterial origins from the aortic trunk, rupture back into the true vascular lumen (which can be lifesaving), extension into the pericardial sac with pericardial tamponade, or rupture into the pleural cavity with devastating hemorrhagic shock and death ([Fig. 33.2A,B](#)).

A thin adventitial wall facilitates external rupture of TAD. Predictors of continuing dissection offer the cornerstones of treatment strategy and include degree of sustained hypertension and upstroke surge pressure (slope of the pulse wave during systole or change in pressure over change in time [dp/dt]). Primary aortic branches along the path of the dissection may become occluded, shear off, or remain in continuity with the true or false lumen. A branch itself may also dissect. Occurrence of the preceding entities combine to produce a wide variety of diverse signs and symptoms associated with thoracic aortic dissection.

Rupture is the most common cause of death during the early acute phase of TAD. The most frequent rupture route leading to death is into the pericardium causing tamponade. Compromise of arch vessels may lead to neurologic

Figure 33.2 Chest radiograph with a widened mediastinum (A) with subsequent rupture of the thoracic aortic aneurysm into the left pleural space (B).

symptoms and injury. Death may also occur with involvement of the aortic root, producing primary ostial compromise and acute myocardial infarction or severe aortic regurgitation. Rarely, fistulas and high-degree heart block may be produced. The thin wall of any residual pseudoaneurysm following TAD tends to enlarge and over time is at high risk of rupture. Total thrombosis of the false lumen is rare, whereas distal reentry into the true lumen may help decompress the false lumen and increase the chance of survival. Postoperative false lumen patency is a predictor of late mortality.¹⁵

DIAGNOSIS

SYMPTOMS

The diagnosis of acute TAD is complicated by the infrequent occurrence of this clinical condition as well as the diagnostic difficulty and is particularly problematic because of the potential catastrophic outcome.¹⁶ Typical symptoms of TAD are excruciating, severe at onset, pain of a sharp and tearing nature. The location of the pain (anterior chest, neck, jaw, inner scapular, and lumbar/abdominal) is linked to the location of the dissection. Symptoms, other than pain, include visceral symptoms (vomiting, diaphoresis, and syncope).

PHYSICAL EXAM

Although physical examination findings may be absent, if present, they are useful in directing the clinician's attention to this diagnosis.¹⁶ Inequality of pulses in the upper extremity and a blood pressure differential of 20 to 30 mm Hg between the two extremities may be seen based on the location of the dissection. A new aortic regurgitation murmur occurs in a significant number of patients. Proximal dissection may also interfere with coronary artery blood flow, producing cardiogenic shock or rupture into the pericardium, producing pericardial tamponade. Pericardial tamponade would be supported by findings of jugular venous distention, muffled heart tones, tachycardia, and hypotension. Mass compression effects can produce findings such as superior vena cava syndrome, Horner syndrome, hoarseness, dyspnea, or dysphagia. Syncope is seen in 1 of 10 cases

of TAD. Syncope likely results from acute cardiac dysfunction or vascular outflow obstruction of the carotid arteries. Vasovagal pain response may also be a potential etiology of syncope. When syncope is related to hypovolemic shock from rupture through the adventitia into the pleural space, the prognosis is grave.

IMAGING

CHEST RADIOGRAPH

The great majority of patients with thoracic aortic dissection has abnormalities on the chest radiograph. A normal chest radiograph may therefore help in decreasing the likelihood of aortic dissection. A study by Klompas looked at 1337 chest radiographs in patients with thoracic aortic dissection and reported abnormalities in 90% of patients.¹⁷ The most common changes associated with dissection are abnormal aortic contour, widening of the mediastinum, pleural effusion, displacement of intimal calcification, abnormalities of the aortic knob, and displacement of the trachea or nasogastric tube to the right. In the absence of an abnormal aortic contour or mediastinal widening, a diagnosis of dissection is less likely.

COMPUTED TOMOGRAPHY

The most common diagnostic modality used for diagnosis of TAD is computed tomography (CT) (Fig. 33.3). A CT angiogram shows high sensitivity and specificity in diagnosis and exclusion of TAD. It is the optimal imaging modality for ruling out aortic dissection in patients with low clinical pretest probability. Limitations of this technique include use of ionizing radiation and contrast media, need for transfer to imaging station, and limited ability to access the aortic valve. Advantages are ready availability, turnaround time, delineation of entire aorta, and diagnosis of other disorders causing the patient's symptoms. Advances in CT angiographic techniques—such as spiral multidetector scanner technology that allows volume-rendered, three-dimensional reconstruction of a CT angiogram—are likely superior to magnetic resonance images (see Fig. 33.4 as an example of the technology).

ECHOCARDIOGRAPHY

Transthoracic echocardiography (TTE) should be performed early in the evaluation of any patient in whom the

Figure 33.3 Computed tomographic angiogram demonstrating a thoracic aortic dissection. This Stanford type A dissection extends from the ascending aorta (large arrow pointing to the intimal flap) to the descending aorta (smaller arrow pointing to the intimal flap).

Figure 33.4 Volume-rendered enhanced image from computed tomographic angiography study showing true (T) and false (F) lumens in the descending thoracic aorta. (From Kapustin AJ, Litt HI: Diagnostic imaging for aortic dissection. *Semin Thorac Cardiovasc Surg* 2005; 17:219.)

diagnosis of ascending aortic dissection is entertained. If a pericardial effusion is present, signs of tamponade can be identified. TTE can help identify aortic dissection if multiple views are obtained—specifically, suprasternal, subcostal, and right parasternal views. The intimal flap may be identified within the lumen, with motion that is not synchronized

Figure 33.5 Transesophageal echocardiogram image showing intimal flap in the ascending aorta extending to the aortic annulus. (Courtesy of Priscilla Peters, Cooper University Hospital, Camden, NJ.)

with the surrounding structures. To minimize the chance of a false-positive result, the flap should be visualized in more than one view. The addition of color Doppler helps to identify flow artifacts (as opposed to an intimal flap) within the ascending aorta by demonstrating flow between the true and false channels at the site of an intimal tear and by showing a difference in the timing or direction of flow within the two lumens.¹⁸ Color Doppler permits detection and quantification of aortic regurgitation. TTE is especially useful for diagnosing dissections involving the ascending aorta but is much less sensitive for descending dissections. If a dissection is not visualized in the patient with chest pain, finding regional wall motion abnormalities may suggest the alternative diagnosis of coronary ischemia.

Transthoracic echocardiography (TTE) (Fig. 33.5) can be performed safely on most critically ill patients in a monitored setting.^{19,20} To avoid precipitating hypertension, tachycardia, or gagging (straining) in a patient with suspected dissection, conscious sedation should be administered. Nearly all of the thoracic aorta can be visualized, including most of the arch. The area from the distal ascending aorta to the midarch, however, is difficult to evaluate with TTE because of interposition of the airway between the esophagus and the aorta.²¹ The sensitivity of TTE for thoracic aortic dissection is close to 100%, but specificity is lower, owing primarily to reverberation artifacts that may be visualized within the ascending aorta, simulating an intimal flap.²² Color flow Doppler with TTE may demonstrate flow through or on either side of the suspected intimal flap (Fig. 33.6). TTE is helpful for evaluating involvement of the coronary ostia and aortic valve. As with TTE, regional and overall ventricular wall motion can be evaluated and the presence of pericardial effusion can be determined.

AORTOGRAPHY

Once the gold standard for diagnosis of TAD, aortography fell into disfavor as the diagnostic study of choice owing to its invasive nature and a relatively high false-negative rate.²³ The sensitivity of aortography is lower than that of CT, and its specificity is no better. Reliance on iodinated contrast does not ensure direct visualization of a thrombosed lumen

Figure 33.6 Image from a transesophageal echocardiogram revealing an intimal flap in the descending aorta. Color Doppler shows flow through two fenestrations in the flap. (Courtesy of Priscilla Peters, Cooper University Hospital, Camden, NJ.)

or intramural hematoma, or occasionally even confirm the presence of a second, false lumen.²⁴ Aortography has had a resurgence with the growth of endovascular intervention in the management of dissections where it facilitates stenting across intimal tears, fenestration of intimal flaps, and opening occluded branch vessels.^{25,26}

MAGNETIC RESPONSE IMAGING (MRI)

The most reliable diagnostic finding with MRI is demonstration of two lumens separated by an intimal flap. Gadolinium-enhanced magnetic resonance angiography (MRA) allows the visualization of blood flow, which can be used to detect the presence and magnitude of aortic regurgitation or to demonstrate communication between the true and false lumens at the site of an intimal tear. An intimal flap can be identified in most cases, except when the false lumen is completely thrombosed. The diagnostic accuracy of MRI for aortic dissection approaches 100%.²⁷ Problematic is (1) that it cannot be performed in patients with pacemakers or defibrillators, aneurysm clips, or ferrous metal implants, (2) claustrophobia, and (3) life support equipment (ventilators, monitors, intravenous infusion pumps) with associated logistical issues. Image acquisition, despite advances in the technology, is more time consuming than with CT. Because it entails no radiation exposure, MRI may be an appropriate initial study in the stable patient²² and for long-term follow-up evaluation.^{22,28}

SUMMARY

Table 33.1 shows a comparison of diagnostic imaging modalities for evaluation of thoracic aortic dissection. The 2010 American Heart Association (AHA) guidelines for diagnosis of dissection give a class I recommendation for using either urgent transesophageal echo, MRI, or CT angiogram to determine a definitive diagnosis in patients with high clinical suspicion.²⁹ If the initial diagnostic test is negative in patients with high clinical suspicion, a second imaging modality should be completed. The diagnosis algorithm from the 2010 guidelines for the diagnosis and management of TAD is shown in Figure 33.7.

PERIOPERATIVE MANAGEMENT

GENERAL PRINCIPLES

Medical therapy is critical for survival with both type A and type B TAD.³⁰⁻³³ Immediate initiation of medical therapy is imperative, both before surgical intervention for type A TAD and as definitive therapy for patients with type B TAD that is uncomplicated. The primary objectives of therapy are rapidly normalizing arterial blood pressure in hypertensive patients and reducing the force of left ventricular contractility in all patients. Following admission to the intensive care unit (ICU), vital signs are monitored continually; blood pressure should be compared between upper extremities, and the same for carotid pulses. Arterial line insertion is indicated. A radial arterial line on the side of higher blood pressure or a femoral arterial line is placed. For type B dissection, a right radial arterial line is preferred. Intravenous drugs are indicated for medical therapy. In order to limit shear force, which is propagating the dissection, it is important to control the rapidity of the rise of the systole, which is done by avoiding tachycardia (goal heart rate is 60 to 75 beats per minute), depressing contractility, and decreasing blood pressure. Because blood pressure is maintained at low normal, a Foley catheter is recommended in order to judge adequate tissue perfusion. Pain is a marker of continued dissection of a TAD, and subsiding of pain can be assumed to be a marker of halting of dissection. Medical therapy is the treatment of choice for uncomplicated type B TAD. It may also be successfully used in patients who are poor surgical candidates or in select patients with uncomplicated and stable type A TAD.

The mortality of nonoperative management of type A dissection may be up to 1% to 2% per hour in the early phase after symptom onset.³⁴ The goals of medical management should be stabilization, management of hypertension, and evaluation of neurologic and metabolic function while the operating room is being prepared for the patient. Most centers favor transport directly to the operating room after the surgical team has been mobilized to avoid any delay that would increase mortality. Exceptions to this rule are patients who may present with severe malperfusion that may preclude operative intervention (severe cerebral or visceral ischemia). These exceptions need to be thoroughly evaluated with CT scan and neurologic consultation if central nervous system issues are present. In the case of patients presenting with severe acidosis and elevated lactate levels, CT scan of the abdomen to evaluate for bowel infarction, which if present may make the patient inoperable, is indicated.

Postoperative management is heralded by the need to prevent hypertension. Life-long control of hypertension will be required. Most patients who undergo type A dissection repair will have evidence of residual dissection within the arch and descending aorta and a 15% risk for progressive aneurysmal dilatation. Blood pressure control over time reduces the incidence of late false channel aneurysm development and decreases the chance of redissection or rupture. Periodic evaluation of the status of the aorta over time following successful therapeutic intervention is needed and is typically done with CT scan. Following surgery, antihypertensive therapy is required immediately, as surgery does not

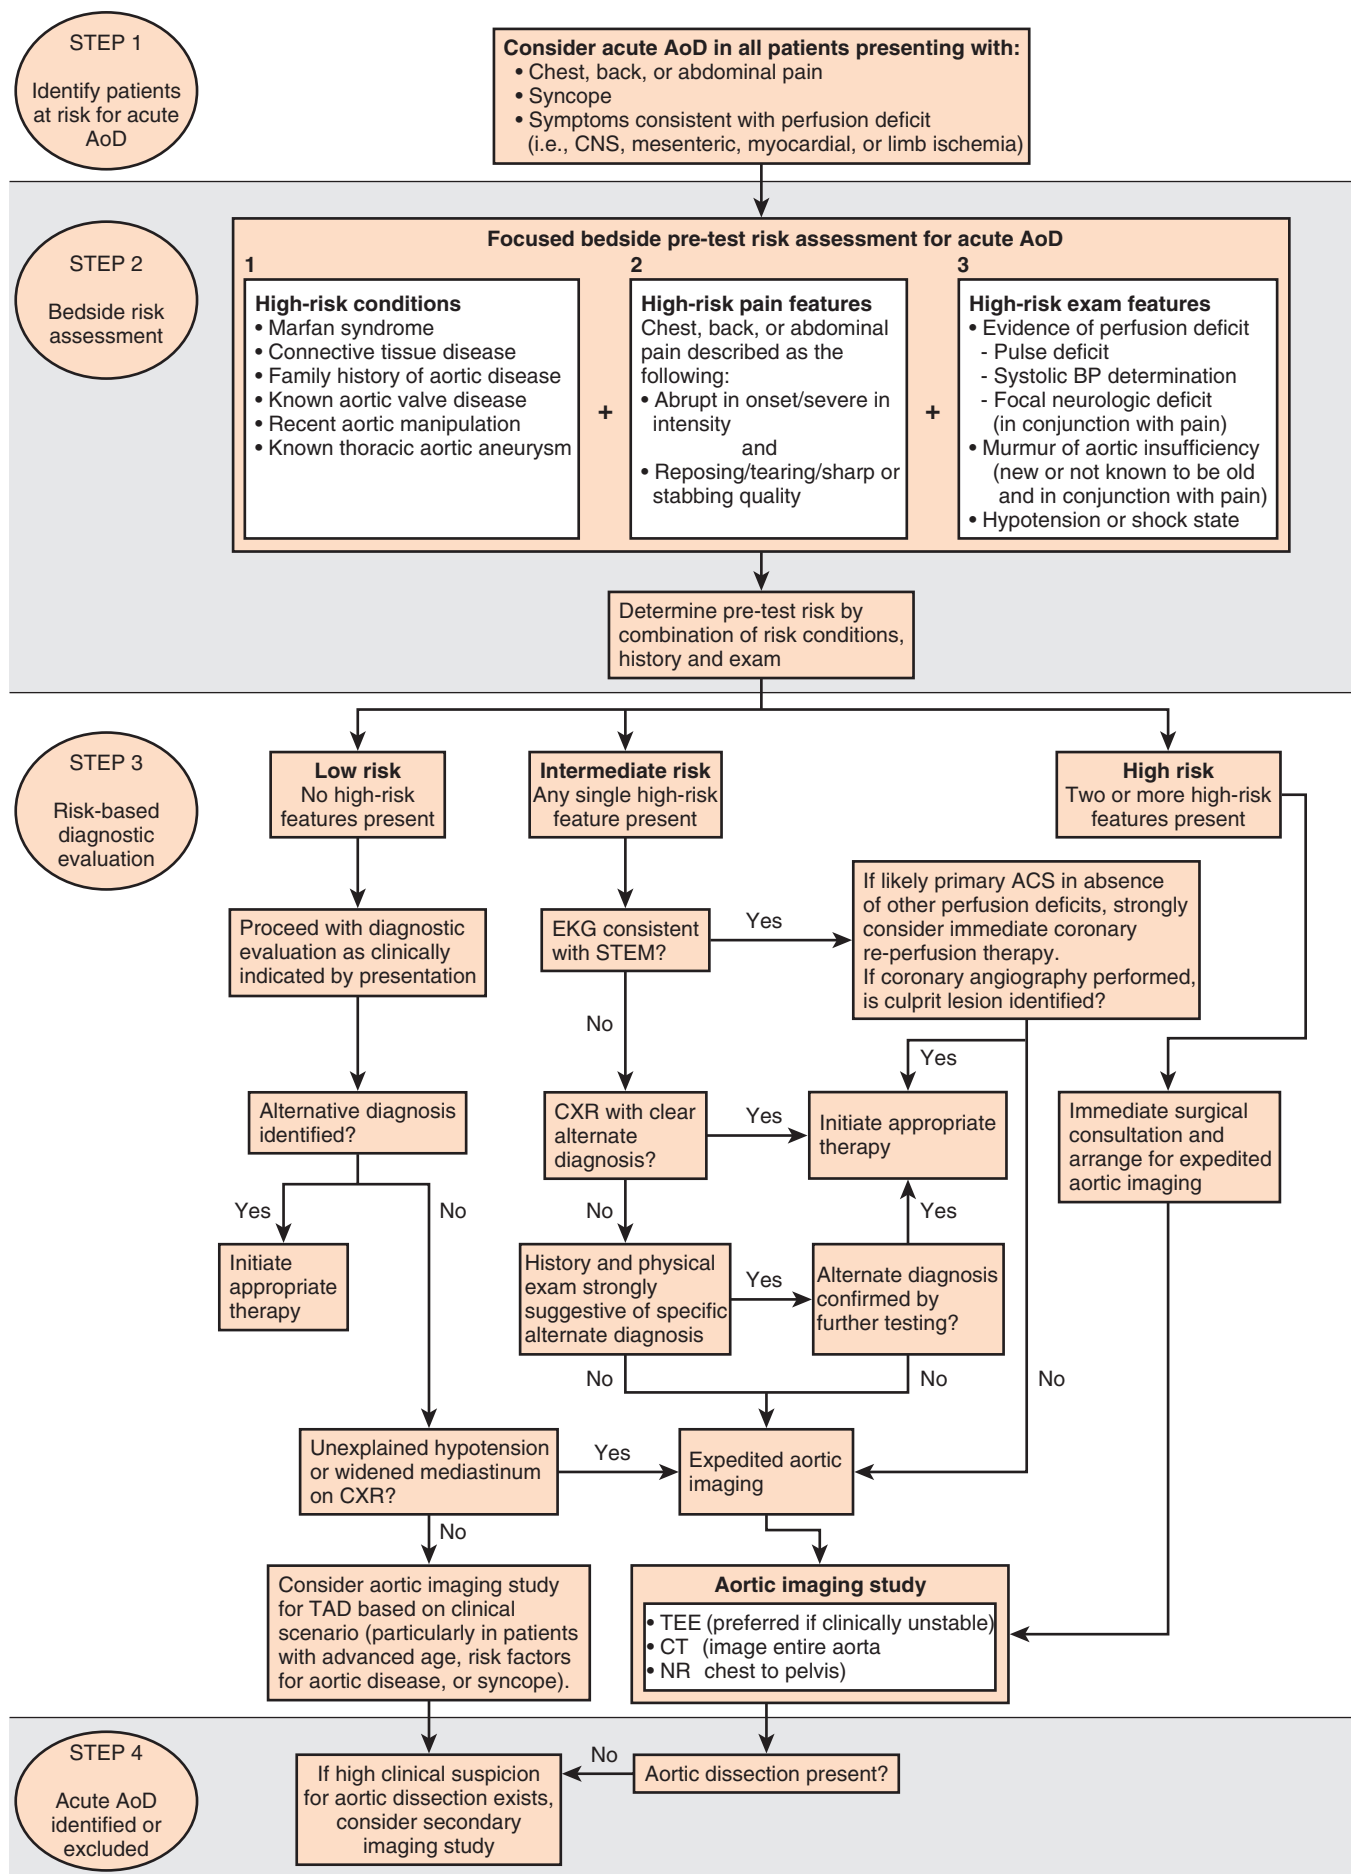

Figure 33.7 Algorithmic flow diagram approach to diagnosis or exclusion of aortic dissection. (Adapted with permission from Guidelines for the Diagnosis and Management of Patients with Thoracic Aortic Dissection. Circulation 2010;121:e266-e369.)

cure the false lumen that persists and leaves the patient at risk for descending thoracic aortic rupture. Signs of persistent pain, new left pleural effusion, or organ hypoperfusion may require a second endovascular procedure to stabilize the residual descending aorta.

SPECIFIC MEDICATIONS

Control of blood pressure and heart rate in the presence of TAD is essential.³⁵ Intravenous beta-blockers are the first line of therapy for aortic dissection and are immediately initiated to avoid tachycardia, which may occur with some medications chosen to lower blood pressure.³⁶ Beta-blockers, in addition to controlling heart rate, also depress contractility and lower blood pressure, both goals of therapy. Intravenous esmolol is the ideal drug as it is a quick onset and short-acting agent and can be titrated to effect. Intravenous diltiazem is an alternative to esmolol for decreasing contractility and avoiding tachycardia when there are contraindications to the use of beta-blockers, such as in the active asthmatic. This target blood pressure will then be anticipated to persist for 6 to 8 hours.

Nitroprusside is the vasodilator of choice for blood pressure control and is begun after the initiation of esmolol when blood pressure lowering is required. Nitroprusside acts by decreasing both preload and afterload. Because it may be associated with reflex tachycardia, it is only added after a beta-blockade is in place. Tachycardia should always be avoided in the presence of aortic dissection. Labetalol is an alternative choice to esmolol plus nitroprusside and is given as a loading dose of 10- to 40-mg boluses (based on degree of blood pressure response) q10 to 15 minutes until target blood pressure is reached or 300 mg is delivered.

Table 34.2 reviews drugs used in the medical therapy of acute TAD.

OPERATIVE APPROACH

ASCENDING AORTIC DISSECTIONS

Surgical intervention is indicated in all patients with proximal dissections, with the exception of patients with serious concomitant conditions that preclude surgery.³⁷ Stroke is the most common contraindication to surgery because there is real concern that anticoagulation (cardiopulmonary bypass) as well as reperfusion can result in further neurologic deterioration by converting the ischemic stroke to a hemorrhagic stroke. Every attempt must be made to perform a careful neurologic assessment prior to undertaking surgical intervention. Additional evidence of severe malperfusion (bowel ischemia) is also a contraindication to surgery.

Preoperative evaluation is essential to assess for the presence of aortic regurgitation, pericardial effusion, the extension of the dissection into the major aortic branches, and the localization of entry and reentry sites, and the presence of thrombosis in the false lumen yields information that can be helpful in planning the surgical approach.³⁸

The operative mortality rate for patients with aortic dissections ranges from 5% to 10% and may approach 70% in cases with complications. The independent predictors of

operative mortality include the presence of cardiac tamponade, the site of the tear, the time to operation, the presence of renal/visceral ischemia, renal dysfunction, and the presence of pulmonary disease.³⁹

Once the diagnosis of ascending aortic dissection is made, cardiac surgical consultation should be obtained and the patient transported directly to the operating room. There is no indication for preoperative cardiac catheterization. Not infrequently patients will present with inferior cardiac ischemic changes (electrocardiogram leads II, III, AVF). Proximal disruption of the right sinus of Valsalva is very common and can result in right main coronary malperfusion. This will also become evident as right ventricular failure or inferior wall ischemia and will be identified on intraoperative TEE. Left main coronary malperfusion is almost uniformly fatal and is infrequently encountered.

Intraoperatively, general anesthesia is induced. In cases where cardiac tamponade is suspected, care must be taken to avoid cardiovascular collapse secondary to a loss of adequate preload when general anesthesia is induced. A TEE probe is then placed and a careful examination is performed. This should include evaluation of right and left ventricular function; extent of the intimal dissection from the sinus of Valsalva to the descending aorta; evaluation of aortic, mitral, and tricuspid valve function; and presence of a pericardial effusion.

Intraoperative planning should involve focus on two key elements: (1) restoration of competent aortic valvular function and (2) resection and reconstruction of all areas of disease in the ascending aorta.

Standard techniques for surgical reconstruction involve cardiopulmonary bypass with circulatory arrest. Arterial cannulation is performed in the femoral artery, innominate artery, or axillary artery. Venous cannulation is usually performed in the right atrium, and cardiopulmonary bypass is then initiated. A cross clamp is then applied across the ascending aorta, and the heart is arrested with retrograde cardioplegia. During this time the patient is then cooled for a period of circulatory arrest. During the cooling period, the ascending aorta is resected down to the sinotubular junction and the extent of dissection is evaluated.

Additionally the aortic valve is evaluated for leaflet pathology, and the sinus of Valsalva must be inspected to determine if this is the origin of the initial intimal tear. The right coronary ostium can frequently be disrupted from the intimal dissection, and if it cannot be reconstructed, coronary artery bypass grafting must be undertaken to prevent ischemia and myocardial infarction.

If there is no primary tear site in the sinus of Valsalva, most surgeons favor reconstruction of the aortic root with glue aortoplasty, and valve resuspension.⁴⁰ Indications for performing a full aortic root replacement with a valved conduit and a left and right coronary artery reimplantation (Bentall operation) include a tear through the sinus of Valsalva or an aortic valve that cannot be reconstructed. This can be performed with a mechanical valved conduit, pericardial conduit, or porcine heterograft.⁴⁰⁻⁴⁴ Valve-sparing aortic root replacement may be also performed in patients who have a long life expectancy. This complex procedure requires resection of all aorta distal to the annulus, creation of neosinuses, and coronary artery reimplantation with reconstitution of aortic lumen continuity.⁴⁵

Reconstruction of the distal aortic arch is performed while on circulatory arrest with the patient cooled to 15° to 25° C. Cerebral perfusion is often maintained during the circulatory arrest period and may be accomplished either antegrade (flow maintained in the axillary or innominate artery) or retrograde (flow through the superior vena cava). Current surgical practice favors the use of the antegrade techniques, as they improve cerebral oxygenation and increase the length that circulatory arrest can safely be performed without neurologic or systemic sequelae.

The distal aortic arch is frequently reconstructed with a glue aortoplasty (such as a hemiarch) or a total arch reconstruction with branch graft reconstruction if there is severe disruption at the level of the cerebral vasculature.

In addition, stent grafting of the distal thoracic aorta may be performed in an antegrade fashion while on a period of circulatory arrest (stented elephant trunk technique). This may stabilize the distal aorta, prevent future aneurysmal dilation, or facilitate a proximal endovascular landing zone for future endovascular therapy should that become necessary.⁴⁶

Following reconstruction of the aortic arch, a Dacron graft is sewn to the distal arch and full cardiopulmonary bypass is reinitiated. The Dacron graft is then anastomosed to the sinus of Valsalva (or valve conduit), thus restoring continuity from the heart to the aortic arch. The patient is then rewarmed and weaned from cardiopulmonary bypass.

DESCENDING AORTIC DISSECTION AND ENDOVASCULAR THERAPY

Uncomplicated acute type B dissection is best managed medically. Approximately 15% of this type of dissection will develop aneurysmal degeneration and require surgical intervention within 5 years of the initial event. The indications for performing early surgery in patients with distal dissections are the rapid expansion of a dissecting aneurysm, rupture into the left chest, impending rupture, persistent and uncontrollable pain, or impairment of the blood flow to an organ or limb.^{37,47-49} Open surgical repair carries extremely high morbidity and mortality, and endovascular stent grafting is the currently favored approach for the acute treatment of malperfusion.^{50,51}

Organ malperfusion and ischemia in patients with aortic dissections are caused by encroachment on the aortic lumen that provides the blood supply to a branch vessel. The lumen supplying blood to the branch vessel may be the true lumen or the false lumen. A stent is deployed through the percutaneous approach within the lumen supplying the branch vessel to hold the lumen open by displacing the intimal flap toward and overcoming the pressure from the other lumen. To overcome the high pressures in the other lumen, a balloon fenestration procedure may be combined with the stent procedure.

The clinical success of endovascular stent placement for aortic dissection ranges from 76% to 100% with a reported 30-day mortality rate of up to 25%.⁵¹⁻⁵⁶ Data on the long-term follow-up of these patients are scarce.

The goals of treatment are coverage of the primary tear site, exclusion of the false lumen, restoration of blood flow to the true lumen, and restoration of organ perfusion and limb perfusion. Covered thoracic stent grafts are usually

deployed from the left subclavian artery to the middle descending aorta. If the initial tear site begins at the origin of the subclavian artery, the proximal landing zone is advanced across the subclavian artery to the left common carotid. If there is evidence of a dominant vertebral system on CT scan, or clinical concern for left arm ischemia, a subclavian to carotid bypass graft can be performed via a separate neck incision. The use of intravascular ultrasound has also gained favor to ascertain that the graft is deployed correctly in the true lumen of the dissection.

About 13% of patients with aortic dissections receive stent-graft treatment, and this proportion is steadily increasing. With more data available and more advancement in operator expertise, stent graft placement may, in the future, become the standard treatment for most cases of distal aortic dissection, because waiting for the complications to occur may not be prudent given that the operative mortality rate in these situations approaches 70%.⁵⁴

TREATMENT OF AORTIC INTRAMURAL HEMATOMA AND ATHEROSCLEROTIC AORTIC ULCER

The treatment of patients with both aortic intramural hematomas and atherosclerotic aortic ulcers is similar to that for patients with classic aortic dissections and depends on the aortic site involved. Both aortic intramural hematoma and atherosclerotic aortic ulcer are more common in the descending aorta and therefore are treated with aggressive medical therapy. Medical therapy should consist of the optimal control of blood pressure (BP), a decrease in aortic pulse dP/dt, as well as close long-term follow-up. Surgery is preferred for the treatment of patients with intramural hematomas and atherosclerotic aortic ulcers in the ascending aorta and aortic arch, and for patients with progressive dilatation and aneurysm formation of the aorta, irrespective of the site of involvement.⁵⁷⁻⁶¹ In a meta-analysis of 143 patients with aortic intramural hematomas, of whom 30 patients (21%) died, 20 deaths (67%) were due to aortic dissection or rupture.⁶²

Interest has also grown in the use of endovascular treatment of type A aortic dissection with short segment stent grafting in high-risk patients.⁶³ Use of short segment grafts to cover an ascending tear is possible if the dissection is limited to the aorta just above the sinotubular junction and there is no associated valvular compromise. Placement may be performed retrograde or antegrade through the ventricle.

OUTCOMES AND PROGNOSIS

The rationale for surgical treatment of acute type A TAD is universally recognized. Patients with acute ascending aortic dissection treated medically fare far worse than those with dissection involving the descending aorta. Little controversy exists over the treatment of choice for the acute type B variety. For most patients, unless life- or limb-threatening vascular compromise is present, medical therapy is considered superior to surgical treatment.^{64,65} If a complication such as rupture necessitating emergency surgery arises, however, the mortality rate is very high. Fortunately, this

occurs infrequently. If operation is required for type B TAD within the first 2 weeks, mortality remains high.⁶⁶ Analysis of all early postoperative complications shows a much lower stroke rate for descending aorta repairs compared to repair of ascending dissections, although the incidence of pulmonary complications and spinal cord injury is higher.

SUMMARY

Aortic dissection is caused by a tear in the intima of the aorta that is propagated by the aortic pulse wave. The aortic pulse wave, or “shearing force,” depends on a combination of myocardial contractility, heart rate, and BP. The risk factors for aortic dissection include advanced atherosclerosis, connective tissue diseases, and aortic coarctation. Dissections involving the area proximal to the left subclavian artery are considered to be type A, and when this area is not involved they are considered to be type B (involving the descending aorta only). Chest pain is the typical presenting symptom, and the classic chest radiographic finding is a widened mediastinum. Diagnosis is best made either with a contrast-enhanced CT scan or a transesophageal echocardiography. Dissection is usually diagnosed utilizing CT scanning with and without contrast enhancement, which demonstrates a grayish white false lumen predominantly filled with a clot alongside a bright white, dye-filled true aortic channel. Dissecting thoracic aortic aneurysms involving the arch and descending aorta that do not interfere with major vessel outflow are typically managed medically with BP control. Aneurysms involving the ascending aorta are typically surgically treated. Aneurysms of the ascending aorta may dissect proximally, producing a murmur of aortic insufficiency or acute pericardial tamponade. Distal migration may produce an obstruction of the major vascular outflow vessels or a rupture into the thorax. Occasionally, a leak may occur into the thorax, which on occasion is diagnosed in time to allow lifesaving surgery. The propagating force for a dissection is the change in pulse over the change in time or the maximum shearing force. This shearing force is minimized by a combination therapy of keeping the pulse in the low normal range, normalizing BP, and decreasing inotropy. Dissection of the aorta is a hypertensive emergency in which normalization of BP is indicated.

KEY POINTS

- Men are at greater risk for developing TAD than are women; approximately two thirds of patients with TAD are male.
- There is an increased risk of type A TAD after aortic valve replacement, especially with larger aortic diameters.
- Rupture is the most common cause of death during the early acute phase of TAD.
- The most common diagnostic modality used to diagnose TAD is computed tomography (CT).

KEY POINTS (Continued)

- Advances in CT angiographic techniques—such as spiral multidetector scanner technology that allows volume-rendered, three-dimensional reconstruction of the CT angiogram—are likely superior to magnetic resonance images.
- The primary objectives of therapy are rapidly normalizing arterial blood pressure in hypertensive patients and reducing the force of left ventricular contractility in all patients.
- Once the diagnosis of ascending aortic dissection is made, cardiac surgical consultation should be obtained and the patient should be transported directly to the operating room.
- In cases where cardiac tamponade is suspected, care must be taken to avoid cardiovascular collapse secondary to a loss of adequate preload when general anesthesia is induced.
- If there is no primary tear site in the sinus of Valsalva, most surgeons favor reconstruction of the aortic root with glue aortoplasty, and valve resuspension.

HYPERTENSIVE URGENCY

INTRODUCTION

Hypertension is a common clinical disorder. Estimates indicate that almost 30% of the U.S. adult population suffers from elevated blood pressure.¹ Furthermore, one third of these patients are unaware of their diagnosis, and of those who are diagnosed and treated, only 34% have adequate control of their blood pressure.² Severe elevations in blood pressure, hypertensive crises, will occur in about 1% of patients with chronic hypertension.^{1,3} Hypertensive crises constitute a clinical problem that the intensivist will encounter in the hospital setting. Unfortunately, a paucity of clinical studies evaluating optimal therapeutic strategies and a lack of consideration for key pathophysiologic aspects have led to common misunderstandings and pitfalls in the management of patients with hypertensive crises.

DEFINITIONS

According to the seventh report of the Joint National Committee (JNC) on Detection, Evaluation, and Treatment of High Blood Pressure, hypertension is classified into three stages: *prehypertension*, *stage 1*, and *stage 2* (Table 34.1).³ The terms *malignant hypertension* and *accelerated hypertension* have been abandoned. These terms were utilized to describe severe elevations in blood pressure associated with advanced retinopathy (Keith-Wagener-Barker stages 3 and 4). Prognosis of these clinical entities has improved dramatically with the advent of effective drugs for hypertension. In addition, studies have demonstrated that retinopathy as measured by the Keith-Wagener-Barker classification does not correlate with severity of hypertension or outcomes.⁴

Hypertensive crises are defined as severe elevations in blood pressure. Although some authors have suggested a diastolic blood pressure (DBP) > 120 mm Hg, it is preferable to evaluate acute elevations of blood pressure within the context of each individual patient and the effects a given blood pressure has on organ function in that patient. For example, an acute raise in diastolic blood pressure to a value of 100 mm Hg can cause significant damage in a previously normotensive individual whereas a diastolic pressure of 130 mm Hg may be tolerated in a patient with a history of uncontrolled hypertension. As we will see, these patients will require different therapeutic approaches. To clarify these situations better, hypertensive crises have been traditionally classified into hypertensive emergencies and hypertensive urgencies.

A *hypertensive emergency* is a severe elevation in blood pressure associated with the presence of acute end-organ damage. Hypertensive emergencies require immediate control of blood pressure, within 1 to 2 hours, to prevent further organ damage. This will usually require the use of intravenous medications and invasive monitoring (arterial line) in a high-dependency unit such as the intensive care unit. The principal systems susceptible to acute end-organ damage from severe elevations in blood pressure include the central nervous, cardiovascular, and renal systems (Fig. 34.1). Several clinical situations are associated with hypertensive emergencies (Box 34.1). The absolute level of blood pressure and the time course of this elevation will determine the development of a hypertensive emergency. However, acute end-organ damage can occur at different blood pressure values in different patients. Therefore, it is more useful to define hypertensive emergencies with the presence of acute end-organ damage as opposed to specified numbers of systolic or diastolic blood pressure. In addition to

Figure 34.1 End-organ failure in hypertensive emergency.

Table 34.1 Classification of Hypertension (Joint National Committee [JNC] 7)

BP Classification	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Stage 1 hypertension	140-159	or	90-99
Stage 3 hypertension	≥160	or	≥100

BP, blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure.

Catecholamine excess states
Postoperative hypertension

initiating immediate therapeutic interventions, patients with a hypertensive emergency may require further diagnostic evaluation to determine the cause of their elevated blood pressure. Depending on the population studied, 20% to 50% of patients presenting with a hypertensive emergency will have a secondary cause of hypertension identified.⁵

A *hypertensive urgency* occurs when severe elevations of blood pressure occur without evidence of acute end-organ damage. In hypertensive urgencies, the blood pressure can be lowered more gradually, over 24 to 48 hours. This can be accomplished usually with oral medications and does not require invasive hemodynamic monitoring in an intensive care unit. Hypertensive urgencies can be associated with

chronic stable organ dysfunction, such as stable angina, chronic renal insufficiency, or previous cerebrovascular accident, without evidence of acute end-organ damage.

PATHOPHYSIOLOGY

The underlying pathophysiology of hypertensive crises is still not fully understood. The transition of mild hypertension or normotension to a hypertensive crisis is usually caused by an event that leads to an abrupt increase in blood pressure. Situations associated with this event may include cessation of hypertensive medications with potential rebound effects, consumption of illicit drugs, and severe pain, as well as several clinical syndromes. Blood pressure is determined by the product of cardiac output and systemic vascular resistance ($BP = CO \times SVR$). In most hypertensive crises, the initial rise in blood pressure is secondary to increased systemic vascular resistance. The rise in systemic vascular resistance is believed to be caused by humoral vasoconstrictors.⁶ With the increase in blood pressure, mechanical stress on the arteriolar wall leads to endothelial damage and fibrinoid necrosis of the arterioles.^{6,7} Vascular damage leads to loss of autoregulatory mechanisms, ischemia, and acute end-organ damage, which prompts further release of vasoconstrictors and initiates a vicious cycle (Fig. 34.2).^{6,7}

APPROACH TO MANAGEMENT

Unfortunately there is a paucity of clinical trials to guide the clinician in the optimal management of patients with hypertensive emergencies. However, a systematic approach with consideration of underlying pathophysiology can help the clinician to avoid common pitfalls in the clinical management of patients with hypertensive crises. The most common pitfall in treating patients with hypertensive crises involves treating numbers without evaluating individual patients for acute end-organ damage. This usually is associated with inappropriate use of intravenous drugs with the potential for precipitous and harmful drops in blood pressure. A methodical approach to patients with severe elevations in blood pressure can help establish safe and effective

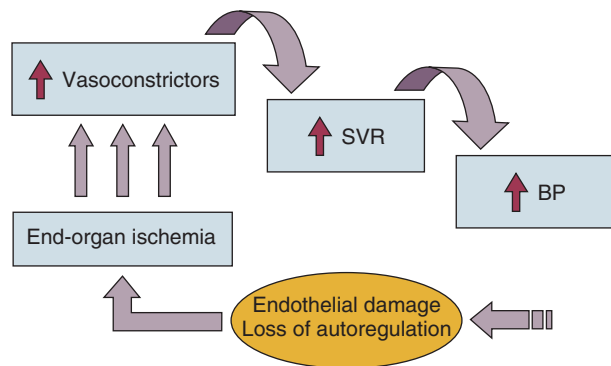

Figure 34.2 Pathophysiology of hypertensive emergency. Increase in humoral vasoconstrictors leads to increased systemic vascular resistance (SVR), which raises blood pressure. As blood pressure increases, endothelial damage results in loss of autoregulation and organ ischemia. Organ ischemia increases release of vasoconstrictors, and a vicious circle is initiated. BP, blood pressure.

treatment. To that effect, the clinician should address three fundamental questions:

1. Should the blood pressure be lowered acutely?
2. How much should the blood pressure be lowered?
3. Which medication should be used to lower the blood pressure?

SHOULD THE BLOOD PRESSURE BE LOWERED ACUTELY?

To answer this question, the clinician must determine if there is evidence of acute end-organ damage. In patients with hypertensive emergencies (the presence of acute end-organ damage), the blood pressure should be lowered acutely to a safe target to prevent further end-organ damage. An organized approach in the evaluation of the patient is necessary. A focused history should determine a previous diagnosis of hypertension, medication history, use of illicit drugs or over-the-counter agents with potential hypertensive effects, and the presence of symptoms consistent with neurologic, visual, cardiac, or renal dysfunction. Physical examination should confirm vital signs. It is important to measure blood pressure adequately and in both upper extremities. Pulses should also be checked in all extremities, as inequalities in blood pressure or pulses can exist with aortic dissection. In addition, a thorough neurologic and cardiopulmonary examination should evaluate possible signs of end-organ failure such as altered mentation, new focal neurologic deficits, or cardiogenic pulmonary edema. A fundoscopic examination of the eyes should be done to look for signs of acute papillary edema or new retinal hemorrhages. A set of simple diagnostic tests can complete the evaluation for acute end-organ damage. An electrocardiogram to rule out active ischemia and a chest x-ray to assess for pulmonary edema or signs of aortic pathology can help the clinician to evaluate the cardiopulmonary system. Abnormalities in blood urea nitrogen (BUN), creatinine, and the urinalysis (red blood cell [RBC] casts) suggest renal involvement. Additional tests may be indicated based on the individual characteristics of each case. An algorithm to establish the presence of

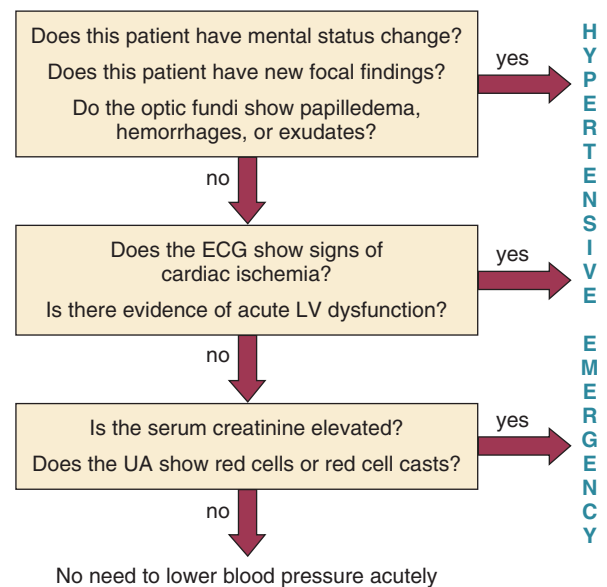

Figure 34.3 Evaluation algorithm for hypertensive emergency. Systematic evaluation for possible acute end-organ damage can proceed according to this scheme. If the answer to any of the questions is “yes,” the patient has a hypertensive emergency and blood pressure should be lowered acutely. If the answer to all questions is “no,” the patient does not have a hypertensive emergency and the blood pressure can be lowered gradually. ECG, electrocardiogram; LV, left ventricular; UA, urinalysis.

acute end-organ damage at the bedside when evaluating patients is presented in [Figure 34.3](#).

If there is evidence of acute end-organ damage based on the clinical evaluation, the patient’s blood pressure should be lowered acutely. However, if after a careful systematic clinical evaluation the exam and diagnostic tests do not show evidence of acute end-organ damage, the blood pressure does not require immediate reduction. It is important to emphasize that the presence or absence of acute end-organ damage and not the numerical value of the blood pressure should dictate the acuity with which blood pressure reduction should be achieved.

HOW MUCH SHOULD THE BLOOD PRESSURE BE LOWERED?

Once the decision to lower a patient’s blood pressure acutely is made, the next step should be to establish a safe therapeutic target for the blood pressure reduction. The goals for treating hypertensive emergencies are to lower blood pressure to a level that prevents ongoing acute end-organ damage and at the same time avoid iatrogenic damage caused by precipitous falls in blood pressure causing hypoperfusion to organs. Understanding the autoregulation of blood pressure in normal states and in patients with chronic hypertension is essential to achieve these goals.

Different organs have the ability to autoregulate and maintain a constant blood flow through a range of mean arterial pressures (MAPs). Under normal conditions cerebral autoregulation will keep blood flow constant between MAPs of 60 to 150 mm Hg.⁸ When the MAP drops, cerebral arteries will dilate, and if the MAP rises, they will constrict

Figure 34.4 Autoregulation of cerebral blood flow. Cerebral blood flow autoregulation curves are depicted for normotensive (solid purple line) and chronic hypertensive (dashed blue line) states.

to maintain constant blood flow to the brain. Drops in the MAP below the lower limit of autoregulation will lead to hypoperfusion resulting in brain ischemia. Rises in the MAP above the higher limit of autoregulation will lead to acute end-organ damage from hypertension (hypertensive emergency). In the case of the brain, this may result in hypertensive encephalopathy. With chronic hypertension, compensatory functional and structural changes will occur in the vasculature.^{9,10} These changes will shift the autoregulatory curve to the right.¹¹ The autoregulatory curve for cerebral blood flow in healthy individuals and in patients with chronic hypertension is shown in Figure 34.4. Hence, patients with chronic hypertension will have a higher tolerance to elevated blood pressures, as their autoregulatory curve is shifted to the right. This explains why many patients present with severely elevated blood pressure and no evidence of acute end-organ damage. However, rapid reductions of blood pressure to “normal” levels can fall below the lower autoregulatory capacity of the circulation in a chronically hypertensive patient. This phenomenon explains the hypoperfusion of vital organs and the development of renal failure or cerebral ischemia often seen when blood pressure is lowered too far or too fast.¹² Based on these principles, most experts would recommend that for most hypertensive emergencies the goal should be to lower MAP by 15% to 25% over a period of several minutes to hours, depending on the clinical situation.¹³ Reduction of blood pressure to normal levels may be warranted in special situations such as those involving patients with aortic dissection or previously normotensive patients with a postoperative hypertensive emergency.

WHICH MEDICATION SHOULD BE USED TO LOWER THE BLOOD PRESSURE?

The ideal medication to treat a hypertensive emergency should have a rapid onset of action, high potency, immediate reversibility, no tachyphylaxis, and minimal or no adverse effects. Although there is no perfect medication, several agents with some of these characteristics are summarized in Table 34.2. There are a limited number of studies

comparing agents in terms of clinical outcomes. With no clear outcome data the selection of a particular agent is based on the clinical scenario, pharmacologic characteristics of the drug, and availability. We will further discuss parenteral agents that are useful in treating hypertensive emergencies (in alphabetical order).

CLEVIDIPINE

Clevidipine is a relatively new agent approved for use in treating severe hypertension during surgery. It is an ultra-short-acting calcium-channel antagonist. Clevidipine has vasoselective properties with a rapid onset of action and a very short half-life (<1 minute).¹⁴ Clevidipine is metabolized by red blood cell esterases; therefore, its use is not affected in patients with renal and/or hepatic failure. Clevidipine reduces blood pressure by a direct and selective effect on arterioles. It does not produce reflex tachycardia, and its effect on reducing afterload is often associated with increased cardiac output. Clevidipine is administered intravenously as a continuous drip. The initial dose is usually 1 to 2 mg/hour with adjustments as needed to obtain the desired response in blood pressure. The maintenance dose is usually 4 to 6 mg/hour; however, higher doses may be required in certain clinical situations. Small studies have compared clevidipine to nitroprusside for the treatment of severe hypertension in anesthetized patients undergoing surgery.^{15,16} These studies showed that clevidipine had similar effects on blood pressure control with less effect on cardiac filling and heart rate. Although clevidipine has not been studied extensively in other clinical situations, its characteristics make it an attractive option for the treatment of hypertensive emergencies outside of the operating room. More recently it seems to have received increased attention in neurologic hypertensive emergencies.^{17,18}

ESMOLOL

Esmolol is an ultra-short-acting cardioselective, beta-adrenergic agent that can be administered intravenously for the treatment of hypertensive emergencies.¹⁹ Esmolol has a rapid onset of action (within 2 minutes), a short elimination half-life (approximately 9 minutes), and a rapid offset of action (within 15 to 30 minutes after stopping infusion).²⁰ Esmolol is rapidly metabolized by red blood cells and is not dependent on renal or hepatic function.²⁰ These properties enable easy titration of the drug and make it attractive in situations of a hypertensive emergency associated with intense adrenergic responses or tachycardia. This agent is available for intravenous (IV) use, both as a bolus and as a continuous infusion. The usual dose is 0.5 mg/kg as a loading dose, followed by a maintenance infusion of 25 to 300 µg/kg/min titrated to the patient's individual response.²⁰ Esmolol has been found to be effective in controlling postoperative hypertension and tachycardia in several clinical studies.²¹⁻²³ Esmolol has also been utilized successfully to treat hypertensive emergencies under other various clinical situations.^{24,25} Esmolol seems to be more effective in situations where both blood pressure and tachycardia are present and there are no problematic issues with beta-blockade (severe systolic cardiac dysfunction or asthma). It is often used in conjunction with other agents to achieve a better response.

Table 34.2 Pharmacologic Agents Utilized in Treating Hypertensive Emergencies

Drug	Dosing	Elimination Half-Life	Onset of Action	Duration of Effect	Advantages	Disadvantages
Clevidipine	Initial dose 1-2 mg/hr with titration. Maintenance dose 4-6 mg/hr	Initial half-life 1 min	2-4 min	15 min	Rapid action, titratable, not metabolized by liver or kidney	Rapidly metabolized in pseudocholinesterase-deficient patients
Esmolol	200-500 µg/kg over 1-4 min, then 50 µg/kg/min for 4 min, and titer, then infuse 50-300 µg/kg/min	9 min	2 min	18-30 min	Easily titratable; cardioselectivity	Use with caution in patients with heart failure or asthma
Fenoldopam	Initial dose, 0.1 µg/kg/min with titration every 15 min, no bolus	5-10 min	5 min	30-60 min	Induces both a diuresis and natriuresis	Use with caution in patients with glaucoma
Labetalol	Bolus 20 mg, then 20-80 mg every 10 min for maximum dose 300 mg. Infuse at 0.52-2 mg/min	5 hrs	2-5 min	2-4 hrs	No reflex tachycardia	Use with caution in patients with asthma, heart failure, or bradycardia
Nicardipine	Initial dose, 5 mg/hr to maximum of 15 mg/hr	40-60 min	10-20 min	1-4 hrs	Minimal cardiodepressant effects; minimal dose adjustments required	Possible adverse effects include hypotension, headache, and flushing
Nitroprusside	Initial dose, 0.25 µg/kg/min, maximum dose 8-10 µg/kg/min	14 min	Within seconds	3-4 min	Immediate onset of effect	Hypotension; coronary steal; cyanide toxicity; light sensitivity; requires frequent monitoring

FENOLDOPAM

Fenoldopam is a selective dopamine agonist that causes systemic and renal vasodilation by stimulating dopamine-1 adrenergic receptors.^{26,27} Fenoldopam is administered intravenously and has a rapid onset of action (5 minutes) and a short duration of action (30 to 60 minutes).²⁷ It is rapidly metabolized by conjugation in the liver to inactive metabolites that are excreted by the kidney. The plasma elimination half-life is approximately 5 to 10 minutes.²⁷ Fenoldopam is administered as a continuous infusion (without a bolus dose), at an initial dose of 0.1 µg/kg/min; this dose is titrated by 0.05 to 0.1 µg/kg/min based on desired effect up to a maximum dose of 1.6 µg/kg/min.²⁶ The most common adverse effects of the drug are related to its vasodilator properties and include hypotension, headache, reflex tachycardia, and flushing.²⁶ Fenoldopam also increases intraocular pressure and should be used with caution in patients with glaucoma.²⁸ Fenoldopam has been demonstrated to be safe and effective in postoperative hypertension.²⁹ Two clinical studies in severely hypertensive patients found fenoldopam to be comparable in efficacy to sodium nitroprusside.^{30,31} Because of its effects on the renal vasculature and its ability to increase urine output, fenoldopam has been proposed as a renal protective drug. A number of small clinical studies report conflicting results in this respect. However, a meta-analysis found improved renal function and mortality in critically ill patients with acute

kidney injury treated with fenoldopam.³² In the setting of a hypertensive emergency, protective effects of fenoldopam on renal function have not been confirmed. However, because it does not affect renal function adversely and does not have increased toxicity in patients with renal failure, it may be a useful alternative to sodium nitroprusside in patients with hypertensive emergency and renal failure.

LABETALOL

Labetalol is a combined alpha- and beta-adrenergic receptor blocker that is currently approved for both oral and intravenous use in the treatment of hypertension. Labetalol lowers blood pressure by decreasing systemic vascular resistance by alpha1-blockade and at the same time counteracts the reflex tachycardia from vasodilation through its beta-blocker effect.^{33,34} Labetalol reduces peripheral vascular resistance while maintaining cerebral, renal, and coronary blood flow. Unlike other beta-blockers, labetalol does not reduce cardiac output. When administered intravenously it has a rapid onset of action (2 to 5 minutes) with peak hypotensive effect occurring within 5 to 10 minutes and lasting 2 to 4 hours.³⁵ The drug is primarily metabolized by the liver and has a plasma elimination half-life of about 5 hours.³³ Labetalol is usually administered intravenously at a loading dose of 20 mg, followed by incremental doses of 20 to 80 mg every 10 minutes until the target blood pressure is achieved or a maximal dose of 300 mg has been reached. An

alternative regimen is a continuous infusion starting at 1 to 2 mg/min and titrated upward to achieve a desired blood pressure end point. Adverse effects of labetalol include orthostatic hypotension, bronchospasm (should be avoided in asthma patients), heart failure, and significant bradycardia (should be avoided in the presence of sinus bradycardia or heart block greater than first degree). Labetalol has been shown to be effective in a wide range of clinical situations associated with hypertensive emergencies.^{33,34,36-39}

NICARDIPINE

Nicardipine is a short-acting calcium channel antagonist that produces selective arteriolar dilation. Nicardipine decreases systemic vascular resistance, without producing reflex tachycardia while maintaining or increasing cardiac output.⁴⁰ Intravenous nicardipine has a rapid onset of action (the major effect lasts 10 to 15 minutes, and the plasma elimination half-life is 40 to 60 minutes), making it easily titratable when treating hypertensive emergencies.^{41,42} An initial dose of 5 mg/hour is recommended, increasing the infusion rate by 2.5 mg/hour every 5 to 15 minutes (to a maximum rate of 15 mg/hour) until the desired hemodynamic response is achieved. Once the target blood pressure is achieved, the infusion rate can be reduced to 3 mg/hour and adjusted to maintain the desired end point. The drug is rapidly distributed throughout the body and is metabolized by the liver into inactive metabolites. Nicardipine should be avoided or used cautiously in patients with aortic stenosis, in patients with cardiomyopathy receiving beta-blockers, and in patients with impaired hepatic function. Several studies have documented the utility and safety of nicardipine in patients with hypertensive emergencies. Randomized studies have demonstrated that nicardipine has similar efficacy when compared to nitroprusside in the management of postoperative hypertension.^{41,43}

NITROPRUSSIDE

For many years sodium nitroprusside was the standard intravenous drug administered for hypertensive emergencies, and it remains a viable alternative today. Nitroprusside is a potent balanced arterial and venous vasodilator that decreases both cardiac afterload and preload. Nitroprusside has a rapid onset of action (2 to 3 minutes) and a short serum half-life (1 to 2 minutes) and may be easily titrated.⁴⁴ Because of its potent effects on blood pressure, use of nitroprusside requires invasive hemodynamic monitoring (arterial line for continuous blood pressure monitoring). Nitroprusside is typically begun at 0.3 µg/kg/min and increased by 0.2 to 1 µg/kg/min every 3 to 5 minutes as needed until a maximum of 2 µg/kg/min. Cyanide and thiocyanate are metabolites of nitroprusside with potential toxic effects. Cyanide is released nonenzymatically from nitroprusside. Cyanide is converted to thiocyanate by the liver. Finally, the kidney excretes thiocyanate. The total dose of nitroprusside and the presence of liver or renal dysfunction increase the risk of toxicity. Cyanide toxicity can be associated with lactic acidosis, mental status changes, and hypotension. Signs of thiocyanate toxicity include delirium, headaches, nausea, abdominal pain, and muscular spasms.⁴⁵ To reduce possible toxicity, the duration of treatment with nitroprusside should be limited and the maintenance rate of infusion should not exceed 2 µg/kg/min. In patients

requiring higher doses of nitroprusside, an infusion of thiosulfate is recommended to decrease the risk of toxicity.⁴⁶ Hydroxocobalamin has also been demonstrated to prevent and treat possible cyanide toxicity associated with the use of nitroprusside. Despite these concerns, nitroprusside has been utilized successfully in the treatment of hypertensive emergencies for many years, and with proper precautions toxicity is seldom encountered.

OTHER AGENTS

Several other agents have been used for treating severely elevated blood pressure. Many of them have been abandoned secondary to the emergence of safer and more efficacious alternatives. However, there are a few agents that despite some limitations compared to the drugs previously discussed may be useful in particular situations. Nitroglycerin directly interacts with nitrate receptors producing predominantly venous dilation. Because of its favorable effects on coronary perfusion and its ability to reduce preload, it is a drug well suited for treating hypertensive emergencies associated with myocardial ischemia or acute left ventricular failure.⁴⁷ Several clinical studies have shown the safety and efficacy of nitroglycerin for the treatment of hypertension after cardiac surgery.⁴⁸⁻⁵⁰ Nitroglycerin is administered as a continuous infusion. The starting dose is 5 µg/min, and this dose can be titrated until a maximum of 200 µg/min is reached. Phentolamine is an α-adrenergic blocking agent that may be used for the management of catecholamine-induced hypertensive emergencies, such as pheochromocytoma.⁵¹ Phentolamine is administered intravenously in 1- to 5-mg boluses. The effects are immediate and may last up to 15 minutes. This drug may cause arrhythmias and angina. Once the blood pressure is controlled, a long-acting α-adrenergic blocking agent such as oral phenoxybenzamine can be started. Enalaprilat is an angiotensin-converting enzyme inhibitor (ACE inhibitor) that can be administered intravenously. Its onset of action is within 15 minutes and its duration of action is 12 to 24 hours.^{52,53} The usual dose is of 1.25 mg IV every 6 hours, titrated by increments of 1.25 mg at 12- to 24-hour intervals to a maximum dose of 5 mg every 6 hours.⁵⁴ The degree of blood pressure reduction with enalaprilat correlates directly with the pretreatment levels of angiotensin II and plasma renin activity.⁵⁵ Enalaprilat is especially useful in hypertensive emergencies associated with scleroderma crises.⁵⁶ Hydralazine is a vasodilator that has been used in pregnancy-related hypertensive crises for many years. However, it has unpredictable effects on blood pressure and a long half-life. Nicardipine and labetalol are better choices for treating pregnant patients with hypertensive emergencies in the intensive care unit.

SPECIFIC CLINICAL CONSIDERATIONS

HYPERTENSIVE ENCEPHALOPATHY

When rises in mean arterial pressure exceed the upper limits of the cerebral blood flow, autoregulatory curve endothelial damage with extravasation of plasma proteins can lead to cerebral edema.⁵⁷ Hypertensive encephalopathy, the clinical manifestation of this phenomenon, is characterized

Box 34.2 Differential Diagnosis of Hypertensive Encephalopathy

Ischemic stroke
Intracerebral hemorrhage
Subarachnoid hemorrhage
Subdural hematoma
Epidural hematoma
Central nervous vasculitis
Brain mass
Seizure disorder
Central nervous system infection
Drug toxicity
Withdrawal syndrome

by headache, visual disturbances, confusion, and focal or generalized weakness. If untreated, hypertensive encephalopathy can lead to coma and death.⁵⁸ Magnetic resonance imaging has demonstrated that the majority of the cases involves the cortical regions of the brain.⁵⁹ However, hypertensive encephalopathy with brainstem involvement has also been described.^{60,61} The differential diagnosis of hypertensive encephalopathy includes several neurologic syndromes (Box 34.2). These should be quickly ruled out with the use of imaging of the brain and other pertinent diagnostic tests. Treatment should be instituted immediately. The goal is to reduce the mean arterial pressure by 15% to 20% within the first 1 to 2 hours.⁶² The hallmark of hypertensive encephalopathy is improvement of symptoms once the blood pressure is controlled. Caution should be taken not to cause worsening neurologic symptoms from hypoperfusion caused by lowering the mean arterial pressure excessively. Drugs suitable for treating hypertensive encephalopathy include nitroprusside, nicardipine, labetalol, and fenoldopam.

HYPERTENSIVE CRISIS IN CEREBROVASCULAR ACCIDENTS

Hypertension is common after both ischemic and hemorrhagic strokes. Extreme elevations in blood pressure have been associated with poor outcomes after ischemic and hemorrhagic stroke.^{63,64} Significant elevations in blood pressure after strokes raise concerns for the potential development of reinfarction, cerebral edema, increased hemorrhage size, or hemorrhagic transformation of ischemic lesions. However, after acute stroke the cerebral vasculature's ability to autoregulate blood flow is impaired.⁶⁵ During this time period, flow to the brain is highly dependent on mean arterial pressure. Even modest reductions in blood pressure can compromise blood flow to the brain during this period with the potential for increased secondary neurologic damage. Optimal treatment of blood pressure during stroke is still not a settled debate. Current guidelines recommend withholding therapy for hypertension in the acute phase of ischemic strokes unless the patient will receive thrombolysis, there is evidence of concomitant acute end-organ damage, or excessive elevations in blood pressure are present (arbitrarily selected as systolic blood pressure > 220 or diastolic blood pressure > 120 mm Hg).⁶⁶ For hemorrhagic strokes, current recommendations are to maintain

Table 34.3 Guidelines for Treatment of Hypertension in Ischemic Cerebrovascular Accidents

Patients Not Eligible for Thrombolysis	
Clinical Parameter	Treatment
SBP < 220 or DBP < 120 mm Hg	No treatment
SBP > 220 or DBP = 121-140 mm Hg	Labetalol or nicardipine to 10%-15% reduction
DBP > 140 mm Hg	Nitroprusside to 10%-15% reduction More labetalol or nicardipine
Patients Eligible for Thrombolysis	
Clinical Parameter	Treatment
Prior to Thrombolytics	
SBP > 185 or DBP > 110 mm Hg	Labetalol or nitroprusside
During or After Thrombolytics	
SBP = 180-230 or DBP 105-120 mm Hg	Labetalol
SPB > 230 or DBP = 121-140 mm Hg	Labetalol or nicardipine
DBP > 140 mm Hg	Nitroprusside

SBP, systolic blood pressure; DPB, diastolic blood pressure.

Table 34.4 Guidelines for Treatment of Hypertension in Hemorrhagic Cerebrovascular Accidents

Clinical Parameter	Treatment
SBP < 180 and DBP < 105 mm Hg	No treatment
MAP < 130 mm Hg	
SBP 180-230 or DBP 105-140 mm Hg	Labetalol, esmolol, nicardipine, enalaprilat
MAP = 130-160 mm Hg	
SBP > 230 or DBP > 140 mm Hg	Nitroprusside
Map > 160 mm Hg	Nicardipine + labetalol

MAP, mean arterial pressure; SBP, systolic blood pressure; DPB, diastolic blood pressure.

MAP ≤ 130 mm Hg in patients with a history of hypertension and a MAP ≤ 100 mm Hg in patients who underwent craniotomy.⁶⁷ Current guidelines are summarized in Tables 34.3 and 34.4.

ACUTE AORTIC DISSECTION

Aortic dissection is a life-threatening complication of hypertension, caused by a tear in the intima of the aorta. This tear is then propagated by the aortic pulse wave. The aortic pulse wave (dP/dt) is dependent on myocardial contractility,

heart rate, and blood pressure. The presenting symptom is usually severe sharp chest pain of abrupt onset. Chest x-ray may be associated with a widened mediastinum. The diagnosis is best made with contrast-enhanced computerized tomography or transesophageal echocardiography.⁶⁸ Aortic dissections are classified as type A (proximal to the left subclavian artery, involving the ascending aorta) or type B (distal to the left subclavian artery, involving the descending aorta).⁶⁹ The goal of treatment is rapid reduction of the pulsatile wave (dP/dt) and aortic stress. Both mean arterial pressure and cardiac output must be controlled in order to achieve this goal and prevent further propagation of the dissection in the aorta. In patients with aortic dissection, the mean arterial pressure and heart rate should be reduced to normal values as quickly as possible. Combining a vasodilator (nitroprusside, nicardipine, fenoldopam) with a beta-blocker (esmolol, metoprolol) is recommended.⁷⁰ All patients with aortic dissection need emergent cardiovascular surgical evaluation. Type A dissections usually require emergent surgery to prevent serious complications such as acute aortic insufficiency, hemopericardium, and cardiac tamponade.⁷¹ Type B dissection is often managed medically. Indications for surgery in type B dissections include complications such as leak, rupture, and impaired flow to vital organs. See Chapter 33.

HYPERTENSIVE CRISES IN PREGNANCY

Hypertension is a common complication of pregnancy and is responsible for 18% of maternal deaths in the United States.⁷² The spectrum of disease varies from mild increases in blood pressure to severe pregnancy-related syndromes with hypertensive emergencies such as preeclampsia and eclampsia.⁷³ Hypertension in pregnancy is defined as a systolic blood pressure ≥ 140 mm Hg or diastolic pressure ≥ 90 mm Hg. Preeclampsia is a pregnancy-specific condition defined by new onset hypertension, proteinuria (>300 mg/24 hours), and pathologic edema during gestation. Eclampsia is defined by the development of seizures or coma in a pregnant patient with preeclampsia. The challenge in pregnant patients with hypertensive crises is to lower the blood pressure in order to prevent maternal end-organ damage while minimizing acute changes in placental perfusion that could negatively impact the well-being of the fetus. Treatment of severe preeclampsia and eclampsia includes delivery of the fetus, magnesium sulfate for the prevention and treatment of seizures, and appropriate blood pressure control. The goal is to reduce the diastolic blood pressure to 100 mm Hg or the mean arterial pressure by 20%. Historically, hydralazine has been preferred in pregnant patients for its safety profile from a fetal perspective. However, data suggest it may not be the most effective or safe agent for this patient population.⁷⁴ For pregnant patients in need of acute lowering of blood pressure in the intensive care unit, drugs such as labetalol and nicardipine are probably better options.^{75,76} Nitroprusside is reserved for refractory cases because of concerns for potential fetal cyanide toxicity. Finally, ACE inhibitors such as enalaprilat are contraindicated in the second and third trimester because of the increase in fetal and neonatal morbidity and mortality.

POSTOPERATIVE HYPERTENSION

Postoperative hypertension deserving of immediate intravenous treatment consideration has been arbitrarily defined as a systolic blood pressure > 190 mm Hg or a diastolic blood pressure > 100 mm Hg on two consecutive readings after surgery. Previous history of hypertension, high body mass index, age, and the grade of surgical stress are recognized risk factors for developing postoperative hypertension.⁷⁷ Severe increases in arterial blood pressure in the immediate postoperative period can result in serious complications such as heart failure, arrhythmia, myocardial ischemia, wound hemorrhage, and cerebral hemorrhage.⁷⁸ Considering the deleterious effects of prolonged postoperative hypertension, many authors have recommended aggressive treatment.⁷⁸ The goal of treatment is similar to other hypertensive emergencies: decrease blood pressure to safe levels and at the same time avoid complications related to hypotension. Although some clinicians feel that postoperative hypertension should be treated aggressively based on the potential for acute end-organ damage, others recommend evaluating for possible causes of hypertension such as pain, hypercarbia, hypoxemia, and urinary retention prior to initiating antihypertensive drugs. As most patients in the postoperative period are unable to take oral medications, even patients with no clear evidence of acute end-organ damage will receive intravenous medications. In patients with previous history of hypertension a reasonable goal is to reduce mean arterial pressure by 20%. In patients with no previous history of hypertension, the goal is to reduce blood pressure to normal levels. Clevidipine, nitroprusside, labetalol, and nicardipine have all been extensively studied in cardiac, vascular, and neurosurgical settings. Nitroglycerin is commonly used in postcoronary bypass surgery, and fenoldopam has been proposed for clinical settings with increased risk of renal ischemia.

CATECHOLAMINE-ASSOCIATED HYPERTENSIVE CRISIS

A hypertensive crisis related to excess catecholamines can result from several causes. Consumption of sympathomimetic agents (amphetamines, cocaine, phencyclidine, and certain diet pills), decongestants (ephedrine, pseudoephedrine), and other agents (atropine, alkaloids) can result in excessive catecholamine release and hypertension. Withdrawal from beta-blocker or alpha-blocking agents can cause a rapid surge in catecholamines and hypertension. In these cases, reinitiation of the particular drug may be sufficient to treat the elevated blood pressure. Additional causes include pheochromocytoma, autonomic dysfunction (i.e., Guillain-Barré syndrome) and ingestion of tyramine in conjunction with monoamine oxidase inhibitor therapy. As a general rule, in catecholamine-related hypertension the use of beta-blockers as initial therapy should be avoided. Loss of beta-adrenergically mediated vasodilation leaves alpha-mediated vasoconstriction unopposed and may cause further elevation in blood pressure. Pheochromocytoma is a rare tumor that produces excess catecholamine and can cause severe hypertension. Symptoms commonly associated with pheochromocytoma include headache, palpitations,

diaphoresis, abdominal pain, anxiety, and hypertension. Some patients may present with orthostatic symptoms. For patients with a hypertensive emergency associated with pheochromocytoma, the drug of choice is phentolamine. Once blood pressure is controlled a beta-blocker can be added to control tachycardia. For less critical situations or after acute hypertension is controlled, the oral agent phenoxybenzamine can be used.

HYPERTENSIVE URGENCY

Hypertensive urgency refers to a clinical situation in which there is severe elevation of blood pressure without evidence of acute end-organ damage. This is a common clinical situation that is often mismanaged. Too often clinicians have the impulse to treat numbers and risk causing more damage to patients from precipitous drops in blood pressure. Despite markedly elevated blood pressure, patients with hypertensive urgency are at low risk of immediate complications. Morbidity from elevated blood pressure occurs over months to years. Therefore, it is more important to start patients with hypertensive urgency on a good long-term oral regimen and reduce their blood pressure gradually over 24 to 48 hours. One must avoid the use of medications that have the potential to produce abrupt drops in blood pressure and cause significant damage from hypoperfusion.^{12,79} In this respect, practices such as the use of sublingual nifedipine in hypertensive urgency have been abandoned secondary to the potential hazards to patients.^{80,81} Often, restarting a previously effective drug regimen is all that is needed to treat hypertensive urgencies. Physicians often feel compelled to treat elevated blood pressures immediately and feel a false sense of security if they see the numbers improve quickly. However, in the absence of acute end-organ damage this therapeutic strategy has a higher potential for causing damage and is not based on a clear scientific rationale.

KEY POINTS

- Hypertension is a common clinical disorder, with an estimated 30% of the U.S. adult population suffering from elevated blood pressure.
- A *hypertensive emergency* is a severe elevation in blood pressure associated with the presence of acute end-organ damage.

KEY POINTS (Continued)

- The treatment of a hypertensive crisis is guided by (1) whether the blood pressure should be lowered acutely, (2) how much it should be lowered, and (3) what medication should be used.
- The ideal medication to treat a hypertensive emergency would have a rapid onset of action, high potency, immediate reversibility, no risk of tachyphylaxis, and minimal or no adverse effects.
- Parenteral agents with specific indications in the treatment of hypertensive crises include clevidipine, esmolol, fenoldopam, labetalol, nicardipine, and nitroprusside.

Physiology and Biology of Wound Healing
Epithelialization and Wound Care
Optimizing Wound Healing

Regionalization within a health care structure allows for more efficient control and use of limited resources. The intensive care unit (ICU) contains specially trained staff and a variety of support devices, such as mechanical ventilators, intra-aortic balloon pumps, ventricular assist devices, and dialysis machines, which in most cases cannot be used elsewhere. Optimally, the location of a patient is determined by matching the patient's needs with a location's resources and expertise.

Generally, the surgical ICU is where experience, staffing, skills, and technology converge to provide services that cannot be provided anywhere else within the hospital. Highly skilled nurses, often greater in number than the patients themselves, work intimately with intensivists and ancillary staff in an environment designed to stabilize, diagnose, and simultaneously treat the most acutely ill patients. ICU management by intensivists allows for improved staff and family satisfaction, reduced complication rates, lower costs, shorter length of stay, improved processes of care, and a morbidity and mortality risk advantage.¹⁻⁴ ICU systems focused on an environment of safety and compliance with evidence-based standards promote improvement in many outcome metrics.⁵ Safe and efficient patient throughput allows for greater institutional procedural volume, which, when paired with surgeon procedural volume, has been shown to be associated with reduced mortality risk.⁶

Classic postoperative indications for ICU admission include advanced age or prolonged duration of the operation, both criteria without specifically defined thresholds. Other factors, such as the need for mechanical ventilation,

volume resuscitation, or administration of vasoactive medications, make ICU care unavoidable. Monitoring of level of consciousness, airway, bleeding, pulses, rhythm, acidosis, urine output, and global perfusion also is facilitated by ICU admission. Identifying patients who may need postoperative ICU care can be difficult. Although there are scoring systems to assess risk and fatality (APACHE, SAPS, MPM, SOFA), it is difficult to apply these predictions to specific disease states or individual patients. Some prediction models utilize physiologic data for patients after admission to the ICU and have not been validated as preadmission screening tools.^{7,8} Physicians may predict mortality risk even better than scoring systems.⁹ In practice, most physicians do not use these tools to determine postoperative ICU admission. Admission criteria based on priority, diagnosis, and objective parameter models have been published by the Task Force of the American College of Critical Care Medicine and the Society of Critical Care Medicine.¹⁰

POSTOPERATIVE EVALUATION

Obtaining a comprehensive medical and surgical history is a fundamental step in understanding a patient in the surgical ICU. The medical record, traditionally written but now more commonly electronic, should contain all of the elements necessary to assemble the story up until the time of ICU admission, although deciphering a chart, particularly when it is long, requires time, patience, and detective skills. Data gathering usually begins by word of mouth from the

providers delivering the patient. Effective “hand-off” is essential to maintain the continuity of care and to ascertain important operative events that may have escaped documentation. It is in fact a standard expected by The Joint Commission.¹¹ Certain questions are common to virtually all admissions:

1. How old is the patient?
2. What are the highlights of the medical/surgical history?
3. Was the operation elective or emergent?
4. What operation was performed, and what are the details of the surgery?
5. Are there any drains?
6. What are the current ventilator settings if the patient is intubated?
7. What medications is the patient receiving currently?
8. Where are the vascular access points? Were they placed under sterile conditions?
9. What was the intubation and anesthetic course like?
10. What were the complications, if any?

Age, comorbid conditions, and emergency operations all affect mortality risk. The details of the operation are key, often aided by diagrams in the chart. Resections, diversions, anastomoses, transplantations, use of prosthetic materials, and other surgical findings are some of the details that should be obtained. In addition, the type and location of each drain must be accounted for. Only by knowing where a drain is placed can a care provider know how to interpret the quantity and quality of the effluent. Each drain or wire must be labeled correctly. Also, the completion of wound closure must be ascertained (skin and fascia closed?). Finally, if the operation was incomplete or intentionally staged, the health care provider needs to inquire about intentions and timing of return to the operating room.

The significance of the anesthesia record should not be minimized. The details about trends in gas exchange, blood pressure, urine output, medications, and summary fluid balance should be reviewed. Always identify if the intubation was easy or difficult. Reviewing the ventilator settings that were used in the operating room sheds some light on any possible gas exchange difficulties and provides a first opportunity to make corrections. Tidal volumes in the operating room are often much larger than those used in the ICU. Identification of current medications and the purpose of each help to formulate short-term therapeutic strategies. Assessing the adequacy of intraoperative resuscitation begins with a review of the quantifiable gains and losses. Resuscitation fluids, blood products, urine output, cavity fluid, and blood losses should all be reviewed. Evaporative and extravascular (third space) losses may be more difficult to accurately quantitate. Major surgical procedures such as bowel resection can require 7 to 8 mL/kg/hour of resuscitation fluid and severe blunt or penetrating injury 10 to 15 mL/kg/hour to match these losses. Underresuscitation may occur in patients with congestive heart failure or anuric renal failure for fear of creating a state of uncorrectable fluid overload. What amounted to adequate resuscitation in the operating room may not be the case by the time the patient arrives in the ICU. A careful reassessment of the adequacy of resuscitation is necessary in virtually all postoperative ICU admissions. Typical postoperative maintenance

intravenous fluid rates are 80 to 125 mL/hour, but can be substantially higher in the presence of ongoing intravascular volume loss. Isotonic fluids are the most appropriate maintenance fluids. It is useful to inquire about the last time the patient received narcotics, benzodiazepines, or paralytics and if reversal agents were given. Finally, any intraoperative laboratory values, particularly ones that require immediate attention, should be reviewed.

When time permits, attention should be directed back to the medical record. The clinician should scan the history and physical examination, progress notes, and consultations to develop a cohesive story line of events that led up to the operation. Did the illness have an impact on nutrition or functional state? How are other comorbid conditions or past operations related to the current presentation? The past medical history and the medication list should be scrutinized; the two are complementary. Inclusion of a disease in the past medical history and absence of an expected medication warrants further investigation (and vice versa). The medication list should be scanned in particular for anti-seizure medications, bronchodilators, antihypertensives, antiarrhythmics, anticoagulants, diuretics, steroids, thyroid replacement, and insulin. It must be decided which medications must be continued in the immediate postoperative period and which can be temporarily delayed. If antibiotics were administered preoperatively, the clinician should identify what they were and how long had they been given and for what indication. In general, if administered preoperatively, bronchodilators, steroids, and insulin are resumed postoperatively. Long-acting antihypertensives should be avoided in the early postoperative period, and short-acting intravenous agents should be used to control hypertension. Diuretics should be avoided in the immediate postoperative period unless directed by invasive monitoring or required because of some other medical necessity. The use of early postoperative beta blockade in patients with coronary artery disease is encouraged if the overall hemodynamic performance allows. Most other medications can be safely delayed until the postoperative patient has shown satisfactory cardiopulmonary performance and stability.

Postoperative laboratory, imaging, and electrocardiogram studies should be selected on a case-by-case basis. Patients who have been moved from operating room table to bed and then transported for any distance are at risk for displacement of tubes and catheters. The admission chest radiograph allows for the evaluation of intravascular catheter and endotracheal, nasogastric, and thoracostomy tube positions in addition to visualization of the pleural, mediastinal, and parenchymal structures. Measurements of blood counts and chemistries are usually routine, but may be deemed unnecessary if preoperative or intraoperative values were unremarkable and the operation was uneventful. Laboratory abnormalities should be followed closely until a favorable trend is established. Patients at risk for perioperative myocardial injury or with new intraoperative arrhythmias should have an electrocardiogram and possibly cardiac enzyme determination.

The physical examination of the patient completes the initial postoperative evaluation. It starts as a cursory survey and concludes as a detailed examination. The examination should expose all parts of the patient that can be accessed, and the examiner should inspect and palpate the patient.

Box 35.1 Support for Adequate Clinical Perfusion

Mean arterial blood pressure >70 mm Hg
 Heart rate <100 beats/minute
 Warm, pink skin without cyanosis or mottling over the digits, thighs, or knees
 Palpable pulses
 Good capillary refill
 Clear yellow urine >0.5-1 mL/kg/hour

Areas that are not under examination should be kept covered to preserve body temperature. If the bed sheets are being changed, it presents an opportunity to examine the back of the patient. An initial assessment of the vital signs, skin, pulses, and urine output provides preliminary insight into clinical perfusion (Box 35.1).

The endotracheal tube, if present, needs to be secured adequately. The health care provider should listen for obvious air leaks around the cuff. The presence of nasal or oral gastric tubes should be noted. All drainage tubes should be identified, and the quality and quantity of output should be scrutinized: Is it serous? Sanguineous? Bilious? Drainage from raw, inflamed surfaces is often serosanguineous. Frankly bloody drainage in quantities of more than 100 mL/hour suggests either surgical bleeding or coagulopathy. All intravascular catheters should be identified with the goal of determining which should be retained for use and which should be removed. Diagnostic catheters often remain unnoticed, and unused, particularly when in femoral vessels. Intravenous catheters not placed under sterile conditions should be removed immediately.

The neurologic examination may be suboptimal if the patient is still under the effects of anesthesia. Reducing or temporarily withholding narcotics and sedation can provide a window to complete a neurologic assessment. If further analgesia or sedation is still required, it may be resumed after the neurologic assessment. However, withholding sedation should not be done in the early postoperative course if it results in a state of competition with care (severe agitation, inability to oxygenate/ventilate, hemodynamic instability).

Intubation, general anesthesia, and mechanical ventilation can result in a variety of airway or parenchymal injuries. Breath sounds should be equal bilaterally. Asymmetry can be caused by atelectasis (possibly endotracheal tube malposition), pleural effusions, or pneumothorax and can be excluded by careful review of the chest radiograph. Examination of the respiratory system should include evaluation of thoracostomy tubes and the mechanical ventilator if present. Except in the case of pneumonectomy, thoracostomy tubes should be placed to suction pending demonstration of sustained lung inflation or resolution of significant drainage. The mechanical ventilator settings and airway pressures should be noted. Adjustments to mechanical ventilation may need to be made to accommodate shivering, metabolic abnormalities, and hypoxia in the early postoperative period. The clinician should ensure satisfactory initial oxygen saturation and avoid excessive tidal volumes. End-tidal carbon dioxide monitoring facilitates adjustment in ventilation and progress in weaning. Routine blood gas

analysis is unnecessary but will be required to manage the more challenging derangements in gas exchange and acid/base disorders.

The cardiovascular examination is primarily directed at assessment of adequate clinical perfusion. Impressions from the initial survey of clinical perfusion plus any available data from invasive monitoring can be used to assess appropriate hourly maintenance fluid rate and the need for further volume resuscitation. Cardiac surgery patients may have mediastinal drains and pacing wires. The former should be connected to suction, and the quantity and quality of drainage should be scrutinized. Pacing wires should be tested for function on admission and can be capped if pacing is not needed. If a postoperative patient comes to the ICU with a permanent pacemaker or an implantable cardiac defibrillator, the device should be interrogated for mode and function at the earliest convenience.

In contrast to the lungs and heart, which can be imaged easily and whose function can be monitored objectively, the abdomen and its contents cannot be evaluated handily. The persistence of anesthesia or administration of narcotics can remove many of the signs and symptoms typically relied on to signal problems. Examination should focus on baseline location and quantity of pain, presence of abdominal distention, firmness to palpation, and quality and quantity of effluent from drains. Bleeding and progressive visceral edema can cause a rapid distention and loss of compliance of the abdomen, often before other findings occur, such as reduction in hemoglobin concentration, urine output, and blood pressure. Frequent follow-up examinations compared with baseline data may be the earliest way of recognizing an intra-abdominal catastrophe. The practitioner should be alert to abdominal distention with associated changes in clinical perfusion (such as low urine output) as a marker of abdominal compartment syndrome. Measurement and trending of bladder pressures can supplement other clinical findings in guiding decision making.

Knowing where the tip of each abdominal drain lies is necessary to evaluate the effluent. A drain lying outside the bowel or biliary system should not drain succus or bile. A drain that suddenly shows these fluids may herald loss of integrity of a surgical repair or de novo perforation. Unexplained or unexpected changes in the quantity of effluent from a drain also are notable.

Abdominal wounds are not always closed at the end of an operation. The clinician needs to determine if the skin or fascia has been left open and, if so, what kind of temporary closure is employed. If a temporary abdominal closure device is used, the quality and quantity of effluent from that device should be examined and documented. It is important to remember that temporary abdominal closure devices are not proof against abdominal compartment syndromes. The provider should be prepared to loosen the outer layers of an abdominal closure or dressing to provide temporary relief. Surgical or traumatic wounds, regardless of location on the body, should be examined for closure integrity, erythema, and induration.

Examination of pulses is important after vascular surgical procedures. Scheduled reassessments should document the presence and strength of pulses. Sudden reduction or loss of pulse signal can represent proximal vascular occlusion, a distal outflow obstruction, or increase in compartment

pressures. Baseline cyanosis and mottling of extremities should be noted for subsequent comparison. In addition, a clinical examination (palpation) of the compartments should be performed to provide the practitioner a baseline for further comparison. Should the mechanism of injury increase the risk of muscle swelling and compartment syndromes, the practitioner can utilize invasive monitoring to measure compartment pressures, and should be prepared to pursue extremity fasciotomies.

Evaluation of a postoperative trauma patient in the ICU can be restricted by the presence of dressings and immobilizing casts and neck collars. Sometimes only toes or fingers are visible for examination. Postoperative admission to the ICU is a good opportunity to look for injuries missed during the initial evaluation and management period. In addition, the practitioner should be alert to potential iatrogenic injuries from intraoperative events; this would include electrical burns from ungrounded cautery circuits, infiltrated intravenous lines, and compression injuries from positioning in the operating room.

RECOVERY FROM ANESTHESIA

POSTOPERATIVE RESUSCITATION

ASSESSMENT

“Adequate resuscitation” is a state, often temporary, that allows for good clinical perfusion and physiologic stability. Patients with good clinical perfusion (expected heart rates, blood pressures, and urine outputs; absence of acidosis) may require no further resuscitation other than maintenance intravenous fluids. The correct maintenance fluid rate will be just enough to match intravascular losses out of proportion to that which is mobilizable from the interstitium but not so much as to needlessly expand the third space or interstitium with edema. Subtle abnormalities in any of these parameters of perfusion may suggest a more serious physiologic derangement warranting further investigation and intervention. Resuscitation is the process of optimizing macroscopic and microscopic metabolic substrate delivery with the goal of avoiding an imbalance between supply and demand. The most fundamental concept is to ensure adequate oxygen delivery (Do_2) and meet the oxygen consumption ($\dot{\text{V}}\text{O}_2$) needs of tissues and organelles. Because the moment when $\dot{\text{V}}\text{O}_2$ exceeds Do_2 is difficult to determine, resuscitation “targets” serve as proxy markers of adequate Do_2 . Resuscitation targets are reproducible, quantifiable values, such as pressures, outputs, metabolites, inflammatory mediators, or oxygen saturations, which represent therapeutic goals. Resuscitation targets provide an important opportunity for study and outcome validation. Despite the seemingly simple logic of employing resuscitation targets, few of these therapeutic goals have been shown to improve clinical outcome. Even routine data derived from a pulmonary artery catheter have not been shown to improve outcome in patients undergoing surgery with decompensated cardiogenic shock or acute lung injury.^{12,13}

MANAGEMENT THEORY

Evaluation and optimization of blood pressure, filling pressures, Do_2 , heart rate, and rhythm often occur

simultaneously, particularly in unstable patients (Fig. 35.1). This may require ongoing volume resuscitation and support with vasopressors and inotropes. Restoration of “normal” blood pressure, heart rate, and urine output, however, do not ensure adequate Do_2 at the level of the microvasculature.¹⁴ Overzealous resuscitation and supranormal Do_2 not only do not improve outcome but also may be detrimental.¹⁵ Not all patients require the same type of resuscitation. Although the fundamental principles are the same, the particular resuscitation technique end points may differ among the different types of shock.^{16,17} Crystalloid resuscitation may be appropriate in septic shock but detrimental in the early resuscitation of penetrating traumatic injury.^{18,19} Even low-volume resuscitation plays a role in the management of patients with penetrating traumatic injury or severe intraoperative hemorrhage.²⁰ Early goal-directed therapy with parameter-specific targets has not completely survived prospective validation. However, the principle of timely intervention remains a cornerstone for virtually all types of resuscitation. End points specific to particular mechanisms of injury can vary significantly.²¹⁻²³

Targeted resuscitation strategies provide an orderly approach to resuscitation, monitoring, and outcome validation. In general, such strategies optimize cardiovascular performance and concurrently measure markers of adequate global Do_2 and $\dot{\text{V}}\text{O}_2$. Increased serum lactate concentration, decreased mixed venous oxygen saturation, and decreased central venous oxygen saturation are the proxy markers for inadequate global Do_2 . However, normal values of mixed venous oxygen saturation and central venous oxygen saturation do not guarantee normal use of oxygen in the tissues, particularly at the regional level. Appropriate targets for microcirculatory resuscitation remain elusive. Noninvasive techniques have reduced the need to obtain physiologic data by the use of a pulmonary artery catheter.²⁴ Pulse and pressure wave analysis along with their derivatives (cardiac output and stroke volume variation) offer a less invasive way of measuring hemodynamic performance and predict volume responsiveness in the appropriate patient population.²⁵ Gastric tonometry, sublingual capnography, near-infrared spectroscopy, and orthogonal polarization spectral imaging are less mainstream technologies available to assess the effectiveness of resuscitation at the regional level.²⁶

Resuscitation products should target the intravascular components that are inadequate, including red blood cell concentrates, platelets, coagulation factors, and acellular resuscitation fluids. Fluid type, bolus volume, and maintenance rate must be individualized. The optimal resuscitation fluid effectively should expand the intravascular space and minimize the inflammatory response (particularly in hemorrhagic shock^{27,28}). All resuscitation fluids leak to some degree out of the intravascular space into the interstitium of the extracellular space. Hypotonic resuscitation fluids are inappropriate for volume resuscitation because of their inability to remain exclusively in the extracellular space. Volume per volume, hypertonic fluids cause more intravascular expansion than isotonic fluids. Hypertonic fluids yield no better outcomes than isotonic crystalloids, however, in the resuscitation of trauma patients.²⁹ Similarly, isotonic crystalloids are at least as efficacious or may be better than colloids to reach the same end points.¹⁴ In trauma, burn,

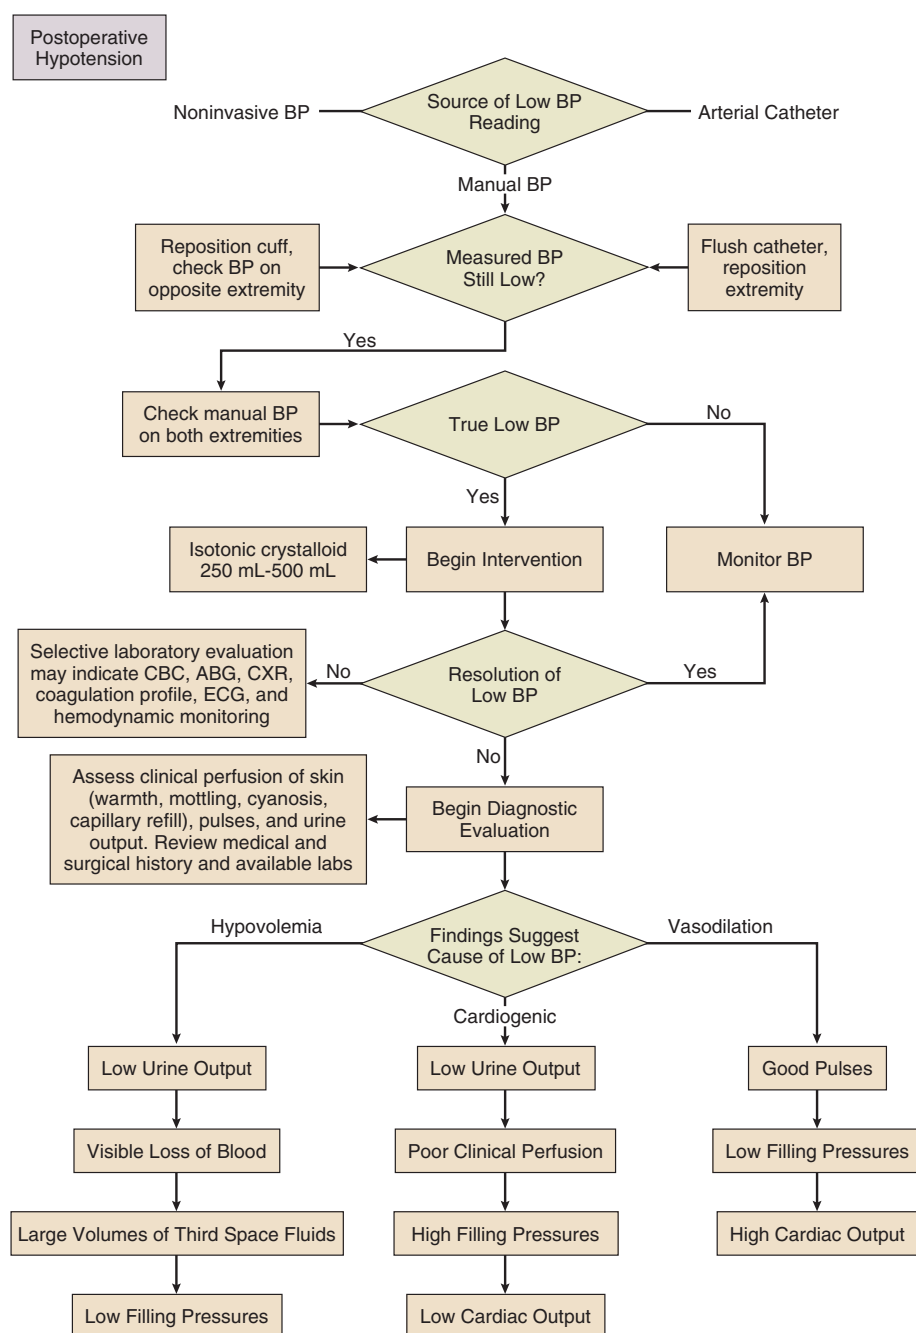

Figure 35.1 Approach to managing postoperative hypotension. ABG, arterial blood gases; BP, blood pressure; CBC, complete blood count; CXR, chest x-ray study; ECG, electrocardiogram.

and general surgery patients, resuscitation with colloids, as compared to crystalloids, has not been shown to reduce the risk of death.³⁰

Metabolic consequences are associated with virtually all resuscitation fluids. Ringer's lactate can activate neutrophils and cause a potent inflammatory response.³¹ Hypertonic saline and dextran combinations cause less of an inflammatory response but any mortality benefit is unproved.^{32,33} Greater than 1 L of hypertonic saline typically results in the development of hyponatremia. Resuscitation exclusively with isotonic NaCl results in a hyperchloremic acidosis. Recent literature has suggested that hetastarch is associated

with greater adverse events when compared to saline resuscitation.³⁴ Hetastarch can cause coagulopathy if greater than 1.5 L is given. All acellular resuscitation fluids, if given in sufficient quantities, cause dilutional anemia. As one can infer from this confusing and sometimes contradictory collection of recommendations, no single resuscitation fluid is satisfactory on its own.

TEMPERATURE CONTROL

Postoperative patients can come to the ICU with moderate to severe hypothermia. Heat is lost in the operating room as a result of vasodilation from volatile anesthetics, cool

intravenous fluids and air temperature, large open surfaces, and evaporation. Excluding patients with potentially anoxic central nervous system injuries,³⁵ hypothermia complicates initial postoperative care by creating an *in vivo* coagulopathy, even when *in vitro* coagulation studies (normalized to 37°C) are normal. In trauma patients, reduction in enzyme activity and platelet function, leading to abnormal fibrin polymerization, occurs at temperatures less than 34°C.³⁶ Care must be taken when administering large volumes of cold blood products or even room temperature crystalloids. Fluid warming devices are available not only to prevent but also to treat hypothermia. All patients with postoperative hypothermia less than 36°C should be actively warmed with forced air blankets, and when normothermia has been achieved, patients should be kept covered to prevent heat loss. Active warming does not cause peripheral vasodilation and subsequent hypotension, and it does not paradoxically cause core cooling owing to heat exchange in cold extremities.

AWAKENING FROM ANESTHESIA

Before completing a successful resuscitation, sedation, analgesia, and anxiolysis should be maintained to facilitate patient comfort and to prevent interference with medical care (e.g., mechanical ventilation or motor activity jeopardizing airway, drains, and intravenous catheters). Selected agents should have minimal hemodynamic sequelae and relatively short duration of action so that frequent neurologic assessment can be performed. Daily interruption of continuous sedation has been shown to reduce ICU length of stay, duration of mechanical ventilation, and incidence of posttraumatic stress disorder.^{37,38}

Narcotics such as fentanyl, morphine, and hydromorphone make ideal first-line analgesics. Delivered by continuous infusion and supplemented as needed, successful analgesia reduces pain-driven tachycardia and hypertension and facilitates cough and deep breathing. The sensation of anxiety is a potent dysphoric stimulus that can result in restlessness and interfere with care. Anxiety can be treated with short-acting intravenous benzodiazepines, such as lorazepam. Very short-acting benzodiazepines, such as midazolam, are less useful because of the dosing frequency necessary to prevent symptoms from returning. It is important not to use scheduled benzodiazepines to treat restlessness due to delirium. This practice can exacerbate delirium and worsen outcomes. Delirium can be identified using simple evaluation tools such as the Confusion Assessment Method for the ICU (CAM-ICU). Competitive restlessness due to delirium is best managed with atypical antipsychotics such as haloperidol, ziprasidone, and quetiapine.³⁹ Persistent restlessness, agitation, or delirium can compete with mechanical ventilation, confound hemodynamic stability, and impede the provision of care. If further reduction of level of consciousness is necessary, propofol or dexmedetomidine can be added and titrated to desired effect. Dexmedetomidine, a weak analgesic, can reduce narcotic requirements.⁴⁰ Propofol, however, has no intrinsic analgesic properties. In a patient who has serious pain, neither propofol nor dexmedetomidine should be used without the concurrent administration of a narcotic. The use of most agents mentioned can be limited by their

tendency to reduce blood pressure and, in the case of dexmedetomidine, decrease heart rate.

When patients are resuscitated adequately, consideration can be given to awakening from residual sedation. On arrival to the surgical ICU or recovery room, unconsciousness, if present, is due to the residual effects of volatile anesthetics, narcotics, benzodiazepines, and paralytics. The effects of volatile anesthetics can persist for 20 to 60 minutes after their discontinuation, particularly if the agent is fat-soluble, the patient is obese, and the surgery was long. Paralytics can have longer than expected duration of action, and this should be suspected when a postoperative patient remains very weak (cannot perform a 10-second head lift) or does not move. A train-of-four twitch monitor can address this issue. Persistent chemical paralysis can be reversed with neostigmine and glycopyrrolate.

Reentry into consciousness may be accompanied by disorientation, anxiety, pain, and varying degrees of restlessness. In the absence of underlying encephalopathy, it is usually possible to get patients to follow commands, answer questions, and participate in the extubation process. The discomfort of an endotracheal tube can lead to unplanned self-extubation. It is important for the bedside care provider to maintain control of the recovery process by ensuring analgesia and anxiolysis. Small doses of narcotic or benzodiazepine or both can usually correct these problems without inducing further sedation and delay of extubation.⁴¹ Patients with encephalopathy resulting from sepsis or shock may not recover a level of consciousness that allows participation in the weaning process. It is controversial whether such a patient should be extubated (avoiding the complications of prolonged extubation) or remain intubated until the ability to protect the airway is more certain. Dexmedetomidine can reduce restlessness without respiratory suppression and may be useful to facilitate extubation of a restless patient. Patients who require sedation for an extended time should receive doses of medication no higher than necessary to achieve the therapeutic target. Sedation scales, such as the Ramsay and Richmond Agitation Sedation Scale,⁴² are useful to avoid oversedation and ultimately promote earlier liberation from mechanical ventilation.

POSTOPERATIVE EXTUBATION

Liberation from mechanical ventilation requires clinical readiness to begin weaning and demonstration of adequate physiologic reserve before extubation. Clinical readiness assesses completion of perioperative tasks at hand and questions any need for early return to the operating room. Resuscitation should be complete, hemostasis should be achieved, metabolic acidosis should be resolving, vasoactive support and gas exchange abnormalities should be minimized, anesthetic agents should be cleared, the ability to protect the airway should be present, and the patient should be awake and reasonably cooperative. These criteria have not been validated clinically, but similar consensus guidelines have been published.⁴³ Daily, if not more frequent, reassessment of clinical readiness is necessary to determine if it is reasonable to consider weaning.⁴⁴

Patients who are ready clinically to progress to extubation should have an assessment of physiologic reserve. Having the patient breathe without mechanical assistance

allows observation of respiratory rate, mechanical coordination of chest and abdomen, vital signs, end-tidal carbon dioxide concentration, and subjective comfort. If the patient was not mechanically ventilated preoperatively, the perioperative course has been uneventful, the patient is comfortable with stable vital signs, no tachypnea or respiratory muscle dyssynchrony is present, and there is no short-term plan to return to the operating room, the patient should begin spontaneous breathing trials and be evaluated for extubation.

Patients who do not achieve these basic criteria may require continued mechanical ventilation that maximizes patient comfort and unloads the respiratory muscles. These patients require a structured, evidence-based approach to ventilator weaning and assessment of adequate physiologic reserve. For more detailed information on weaning, refer to Chapter 43.

BEST PRACTICES

Achieving optimal outcomes should be pursued by providing optimal care. This is especially true for patients with longer length of stay. Effort should be expended pursuing interventions that have been shown to reduce complications, cost, morbidity, and mortality risk. Because a postoperative ICU patient is different in many ways from other ICU patients, some of these fundamental practices are applied with slight nuance and warrant additional mention.

PREVENTION OF VENOUS THROMBOEMBOLISM AND DEEP VENOUS THROMBOSIS

All postoperative ICU patients should be considered for venous thromboembolism (VTE) or deep venous thrombosis (DVT) prophylaxis. The risk of postoperative VTE depends upon both the type of procedure and modifying attributes such as age, prior VTE, history of cancer, obesity, or hypercoagulable state. Risk has been quantified and grouped based on the Modified Caprini Risk Assessment Model.⁴⁵ Low-risk general and abdominal-pelvic surgery patients should receive intermittent pneumatic compression (IPC) over no prophylaxis or anticoagulant-based prophylaxis. Moderate-risk general and abdominal-pelvic surgery patients should receive anticoagulant-based prophylaxis. Low-dose unfractionated heparin, low-molecular-weight heparin, or fondaparinux should be started in the absence of postoperative bleeding. High-risk general and abdominal-pelvic surgery patients should receive low-dose unfractionated heparin three times a day, low-molecular-weight heparin, or fondaparinux. The highest risk patients should receive mechanical prophylaxis via IPC devices, in addition to low-dose unfractionated heparin, low-molecular-weight heparin, or fondaparinux. In general surgery patients with a high risk of postoperative bleeding, mechanical prophylaxis should be the initial preventive modality until the risk of bleeding has decreased enough to allow for anticoagulant prophylaxis.⁴⁶

Neurosurgical procedures or the use of neuraxial analgesia also require special consideration. Anticoagulant prophylaxis should not be in effect while epidural catheters are placed or removed and should be used with caution while an epidural catheter is in place. Patients

undergoing intracranial surgery should receive mechanical prophylaxis with sequential compression devices. Anticoagulant prophylaxis should be added in neurosurgical patients at high risk for VTE/DVT beginning 24 hours postoperatively.

Trauma patients constitute an extremely heterogeneous group, making it difficult to study the strategies of VTE/DVT prophylaxis. There is disagreement in the literature about valid independent risk factors for VTE/DVT in trauma patients. Older age, spinal fractures, spinal cord injuries, traumatic brain injuries, prolonged mechanical ventilation, pelvic fractures, venous injuries, and multiple major operative procedures are often cited. In trauma patients, there are few large, prospective, randomized studies validating the efficacy of any method of VTE/DVT prevention.⁴⁷ Low-dose unfractionated heparin, which has proven efficacy in the general surgery population, is no better than absence of prophylaxis in a trauma patient.⁴⁸ Low-molecular-weight heparin given twice daily does offer a statistical benefit, however, in the prevention VTE/DVT in trauma patients.⁴⁹ Trauma patients without significant risks for bleeding should begin anticoagulant prophylaxis or postoperatively. Data are insufficient to make recommendations as to when anticoagulant prophylaxis in trauma patients with brain injury or liver or spleen fracture is safe. Waiting 24 hours after bleeding has ceased is a conservative time to delay.⁵⁰ In trauma patients at high risk for bleeding, mechanical prophylaxis can be used, although benefit is unproved. Note that IPCs cannot be applied to lower extremities with fractures, fasciotomies, or external fixators. Compression devices applied to the feet may be used as a substitute for IPC but have not been shown to be as efficacious as leg devices. In selected trauma patients expected to have prolonged immobilization or with significant risks for bleeding, inferior vena cava filters may be placed as VTE prophylaxis.³⁰ Inferior vena cava filters should not be used as a primary prophylactic strategy in trauma patients.²⁹ If available, removable filters should be considered, despite the low removal rates. In a trauma patient at high risk for VTE/DVT, the addition of mechanical prophylaxis to anticoagulant prophylaxis may be useful, but synergistic benefit is unproved.

STRESS ULCER PROPHYLAXIS

Stress-related mucosal disease (SRMD) is manifest as diffuse gastric mucosal petechiae, erosions (loss of epithelium, necrosis, and hemorrhage), and discrete ulcers. SRMD can progress to clinically significant bleeding resulting in hemodynamic instability and need for transfusion. It can develop as early as 24 hours after ICU admission. Patients at risk for SRMD include critically ill patients who require mechanical ventilation for greater than 48 hours; patients with coagulopathy, traumatic brain or spinal cord injury, or severe burns; and patients with a history of gastrointestinal bleeding or ulceration within the past year. Minor risks include sepsis, corticosteroids, and prolonged ICU admission.⁵¹ The risk of clinically significant bleeding increases with the severity of illness, duration of mechanical ventilation, increased length of stay, and low intragastric pH. Hemodynamic compromise secondary to acute blood loss occurs in only a small percentage of patients with SRMD, but it is associated with a significantly increased mortality rate.⁵²

Because of the morbidity and mortality rates associated with the complications of SRMD, it is important to identify patients at risk for SRMD and employ effective prophylaxis before bleeding occurs. Although early enteral nutrition has many benefits, the effects of enteral nutrition on SRMD are controversial and should not be used as a sole prophylactic strategy.⁵³ Pharmacologic prophylaxis targets mucosal protection or the suppression of acid secretion. Proton-pump inhibitors may be a good first choice for SRMD prophylaxis owing to degree of acid suppression, duration of action, lack of tolerance, and cost. Parenteral H₂ receptor antagonists may offer a cost advantage over proton-pump inhibitors. Prophylaxis with sucralfate is not preferred because of the efficacy profile of acid-suppression therapies and a higher rate of bleeding with sucralfate prophylaxis.

PREVENTING NOSOCOMIAL PNEUMONIA

The most significant risk for hospital-acquired pneumonia (HAP) in the postoperative patient is mechanical ventilation. Other significant risks include age more than 70 years, chronic lung disease, and depressed levels of consciousness. Though gastric acid suppression is also associated with an increased incidence of HAP, withholding ulcer prophylaxis can hardly be avoided in the patient mechanically ventilated for more than 48 hours.⁵⁴ Postoperative patients should be encouraged to take deep breaths, cough, ambulate, and use incentive spirometry. Semirecumbent body positioning, keeping the head of bed elevated more than 30 degrees, has been shown to reduce ventilator-associated pneumonia in mechanically ventilated patients.⁵⁵ Placing the bed in reverse Trendelenburg position can simulate this elevation without flexing the back, as could be difficult in trauma patients or patients with large open abdomens. Iatrogenic spread of bacteria that can cause pneumonia can be reduced by the enforcement of handwashing and by the use of appropriate barrier protection when performing procedures.⁵⁶ Before deflating the cuff of an endotracheal tube for tube removal or position change, ensure that secretions are suctioned clear from above the cuff.³⁶ Endotracheal tubes designed to provide drainage to the subglottic area above the tube's cuff have been shown to reduce the risk of ventilator-associated pneumonia.^{57,58} The use of 0.12% chlorhexidine oral rinse has been associated with reductions in the rate of ventilator-associated pneumonia in surgical ICU patients and should be part of good oral hygiene.⁵⁹ Although there is evidence that selective digestive decontamination beyond the oropharynx also can reduce the risk of ventilator-associated pneumonia, it is unclear how the routine use of this technique would affect antimicrobial resistance.⁶⁰ The use of noninvasive ventilation in patients with exacerbations of chronic obstructive pulmonary disorder and congestive heart failure is associated with reductions in rates of nosocomial pneumonia, but there are few studies evaluating application of this technique in the management of postoperative respiratory failure.⁶¹

MANAGEMENT OF AGITATION AND DELIRIUM

Delirium is a major problem in postoperative ICU patients.⁶² Previously believed to be an expected and unavoidable result of critical illness that resolves with clinical improvement, it is now known to be a significant marker of increased

morbidity,⁶³ resource use, and long-term cognitive deficit. Delirium is an acute, variable change in mental status with inattention and either altered level of consciousness or disorganized thinking. Delirium can be hypoactive or hyperactive, the majority of patients being in the former group. Occurring in about 70% to 80% of ICU patients, delirium had been underdiagnosed until validated assessment tools such as the CAM-ICU became available.⁶⁴ Delirium is believed to be due to imbalances between the stimulatory and inhibitory neurotransmitters, particularly an increase in dopaminergic and decrease in γ -aminobutyric acid and cholinergic activity. Risk factors include age, preexisting dementia, sepsis, metabolic abnormalities, and medications. The use of benzodiazepines, narcotics, anticholinergics, and antipsychotics is associated with a substantial increase in risk. It is currently unclear whether prevention or treatment of delirium changes clinical outcomes such as fatality and long-term cognitive deficits.

Preventive strategies include avoidance of hypoxemia (Fig. 35.2), correction of metabolic disturbances, and adequate pain control. In addition, environmental normalization with minimization of unnecessary physical and auditory stimulation, restoration of sleep/wake cycles, frequent reorientation (particularly with family involvement), and early mobilization can help decrease rates of ICU delirium.⁴² Pharmacologic treatment of delirium is suboptimal because the same medications intended to reduce disorganized thought may simultaneously increase sedation, prolonging the undesired state. Benzodiazepines may aggravate disorganized thought and should not be used to treat delirium. Haloperidol is the most commonly prescribed neuroleptic to treat delirium,⁶⁵ although its efficacy is yet to be validated. Other atypical antipsychotics such as olanzapine, quetiapine, ziprasidone, and risperidone have also recently gained popularity.^{66,67} Until efficacy of any pharmacologic intervention is shown, medications should be used in the lowest doses possible for as brief a time as possible.

MANAGEMENT OF BLOOD GLUCOSE LEVEL

Hyperglycemia in a critically ill patient can be due to diabetes mellitus (established or new) or stress-induced release of counterregulatory mediators. It is associated with increased mortality risk after acute myocardial infarction, stroke, and severe traumatic brain injury. Hyperglycemia also is associated with reduced functional outcome after neurologic injury, the development of polyneuropathy in critically ill patients, increased rates of infectious complications in the postoperative period, and defective collagen formation in wound healing. Earlier studies⁶⁸⁻⁷⁰ about the benefits of intensive insulin therapy had been published touting improved outcomes, but more contemporary evidence has shown results to the contrary.

Blood glucose less than 60 mg/dL occurs up to 32% of the time when intensive insulin strategies are utilized. Hypoglycemia can have a negative impact on mortality risk and neurologic outcome.⁷¹ Identification of appropriate blood glucose target ranges and management techniques has required the prospective study of thousands (NICE-SUGAR)⁷² of medical and surgical patients. From this data, and other meta-analyses, we can make some observations and logical management recommendations. Intensive insulin treatment, targeting a blood glucose of 80 to

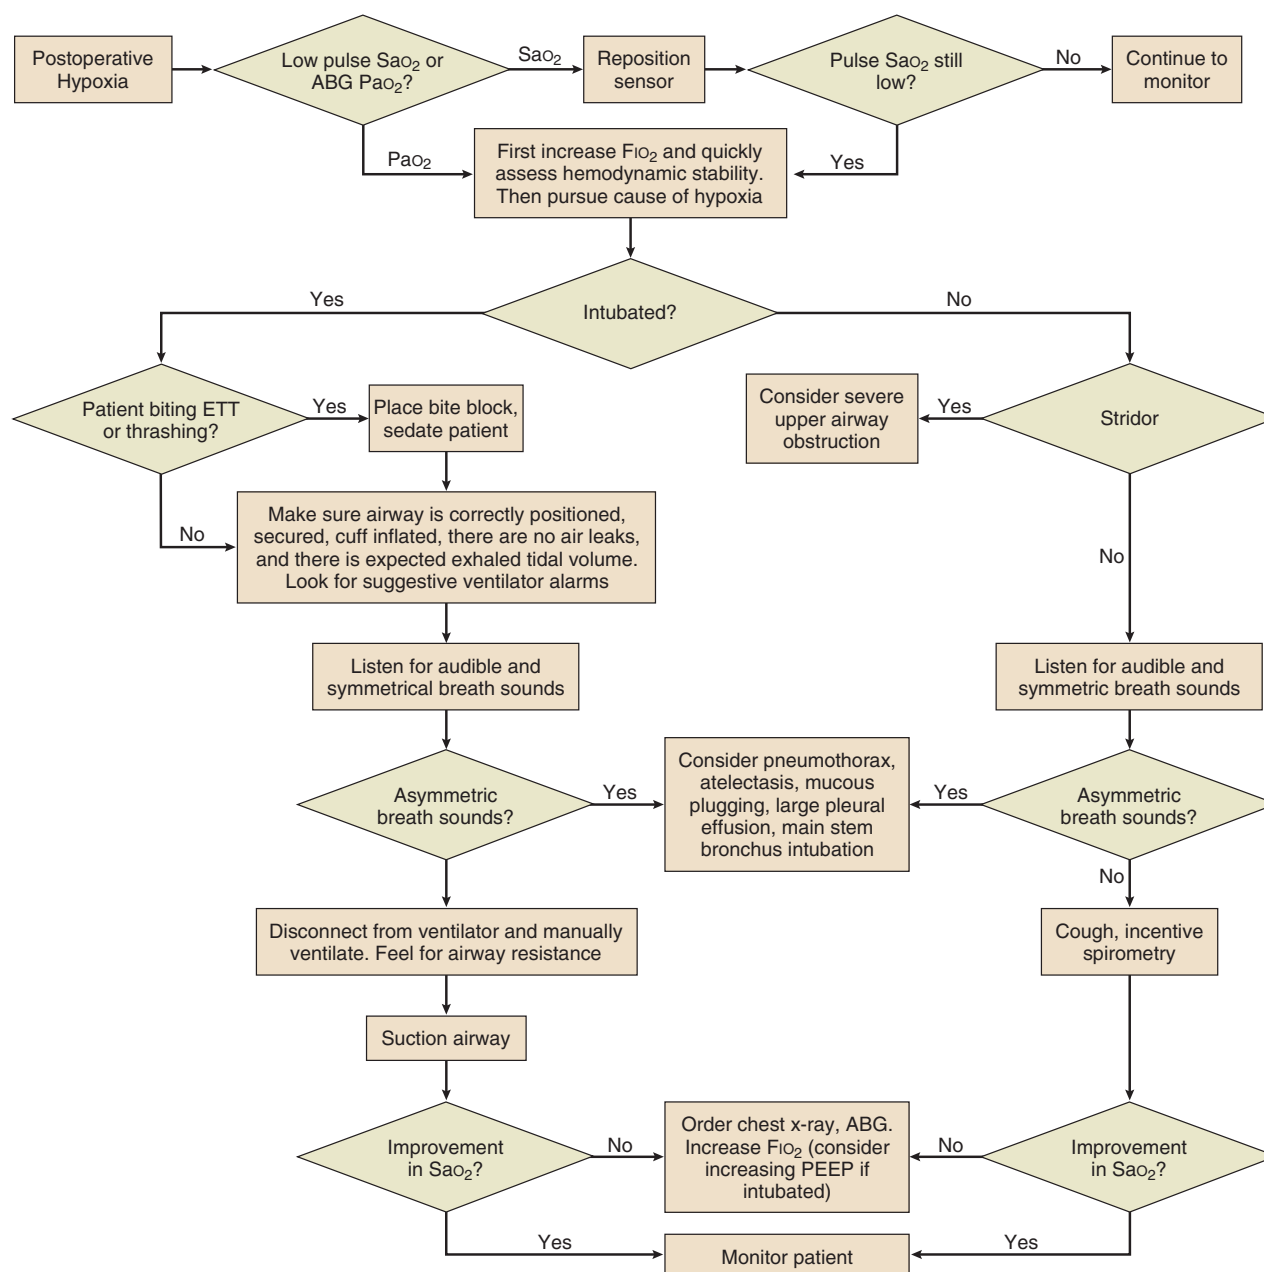

Figure 35.2 Approach to managing postoperative hypoxemia. ABG, arterial blood gas; ETT, endotracheal tube; FiO_2 , fraction of inspired oxygen; PaO_2 , arterial oxygen tension; PEEP, positive end-expiratory pressure; SaO_2 , arterial oxygen saturation.

110 mg/dL, increases the incidence of episodes of severe hypoglycemia and either has no effect on mortality risk or increases mortality risk when compared to more liberal blood glucose target ranges of 140 to 180 mg/dL and 180 to 200 mg/dL.

A rational approach to the management of blood glucose begins with minimizing causes of hyperglycemia such as unnecessary dextrose in intravenous fluids, choosing appropriate balances of carbohydrates and fats in the diet, and avoidance of overfeeding. Blood glucose targets in the 140 to 180 mg/dL range and an insulin regimen that minimizes hypoglycemia appear to be the most beneficial strategy.

Unreliable subcutaneous absorption, extreme or labile hyperglycemia, and inconsistent caloric intake are reasons to use short-acting, continuous intravenous insulin rather

than slower-onset, longer-acting subcutaneous insulin. The treatment of hypoglycemia also needs to be considered an urgent therapy.

POSTOPERATIVE NUTRITION

Postoperative surgical patients are exposed to unique nutritional challenges as a result of the enhanced metabolic demands of wound healing and the abnormalities of bowel motility, anastomotic function, and swallowing. Nutritional support provides calories for metabolic processes, reduces catabolism of protein stores as an energy source, supplies substrate for anabolic processes, and provides an opportunity to reduce net protein losses in the face of ongoing

protein catabolism. In an otherwise well-nourished postoperative patient, beginning nutritional support may be unnecessary, unless it is anticipated that oral intake at nutritional goal would be delayed for 7 days.⁷³ There are considerably fewer studies showing nutritional support strategies that work in the postoperative patient than ones that do not work.⁷⁴

TIMING AND ROUTE

There are three routes of nutritional support—enteral nutrition (including nasogastric tube or postpyloric tube), parenteral nutrition, and oral feedings. With respect to outcomes, it is important to consider not only the route of administration but also the timing. Neither enteral nutrition nor parenteral nutrition seems to have an effect on *mortality* rates whether given preoperatively or postoperatively.⁷⁵ *Preoperative* nutritional support seems to benefit only severely malnourished patients by reducing complication rates.^{76,77} Parenteral nutrition, which requires vascular access, is associated with complications related to non-catheter-related infection and catheter-related bloodstream infection. In addition to avoiding the complications associated with parenteral nutrition, enteral nutrition possibly reduces gut mucosal atrophy and up-regulates gut-associated immunity. In theory this protects against infections elsewhere by the common mucosal immune hypothesis.⁷⁸ In perioperative patients, sufficient evidence is lacking, however, to suggest that the effect of enteral nutrition on the gut barrier has any outcome advantage over parenteral nutrition.^{79,80} Enteral nutrition has been shown to be associated with a lower risk of infection compared with parenteral nutrition.⁸¹ Early enteral nutrition also has been shown to be associated with a shorter length of stay and lower incidence of infections compared with delayed enteral nutrition.⁸² Enteral nutrition is the preferred route over parenteral nutrition because of the reduction in complications and cost. Early postoperative parenteral nutrition does not improve clinical outcomes and should be reserved only for patients who are unable to receive timely enteral nutrition.⁸³

The combination of parenteral nutrition and early enteral nutrition has no advantage over early enteral nutrition alone in patients who are not malnourished.⁸⁴ Patients who are malnourished or are not expected to be tolerating enteral feedings at nutritional goal by about postoperative day 7 should begin parenteral nutrition. If otherwise adequately nourished postoperative ICU patients are expected to be tolerating enteral feedings at nutritional goal by postoperative day 7, early parenteral nutrition may not provide substantial benefit. Finally, patients who are able to tolerate enteral feedings but are unable to tolerate an amount equal to the nutritional goal require supplemental nutrition, typically parenteral nutrition.

When the decision is made to deliver enteral nutrition, tube feedings should be increased quickly in volume to reach nutritional goal. The initial destination for enteral nutrition is the stomach. Nothing about laparotomy itself precludes enteral nutrition with the return of bowel function (e.g., bowel sounds, flatus). Although bowel motility continues through surgery or returns shortly thereafter, gastroparesis is common postoperatively and may result in

delayed gastric emptying. It may be recognized by abdominal distention, high daily nasogastric output (>500 mL/day), or high residual volume in the stomach (>300 mL). Gastroparesis has the potential to delay achieving delivery of adequate enteral nutrition and has resulted in a trend toward delivering enteral nutrition via a postpyloric route. There are recent data to suggest that postpyloric feedings in patients with severe traumatic brain injury reduces the incidence of overall and late pneumonia and in addition improves nutritional efficacy.⁸⁵ Other data suggest that there is no clinical benefit to postpyloric feeding with respect to incidence of pneumonia, ICU length of stay, mortality rate, or time to reach nutritional goal compared with the prepyloric route.⁸⁶ Evidence to demonstrate the clinical benefit of postpyloric to prepyloric feedings is possibly still equivocal. Gastroparesis often can be improved with prokinetic agents, such as metoclopramide or erythromycin.⁸⁷ It is reasonable to continue gastric enteral nutrition in the presence of gastric residual volumes of 150 to 300 mL as long as the patient is not experiencing nausea, vomiting, or progressive abdominal distention or has any evidence of functional gastric outlet obstruction or ileus. The nasogastric route of feeding is preferred, but if establishing stomach function is anticipated to be problematic, implantation placement of a jejunostomy feeding tube should be considered during laparotomy.

FEEDING CONSIDERATIONS IN GENERAL SURGERY PATIENTS

ESOPHAGUS

Patients requiring esophageal resection may present with some degree of malnutrition. It is important to resume nutritional support as soon as technically possible after the operation. These patients have fragile anastomoses in their chests, however, which usually have a suction catheter placed across the repair to decompress the postanastomotic structures. An oral diet is delayed to ensure mechanical integrity of the anastomosis. Some patients have a distal feeding tube placed at the time of surgery so that enteral nutrition does not need to be delayed. Patients who cannot receive oral or enteral nutrition by postoperative day 7 should be considered for institution of parenteral nutrition.

STOMACH

Gastric surgery may result in delayed gastric emptying. Vagal denervation can cause some degree of gastroparesis, and functional outlet obstruction may occur owing to edema at the site of anastomosis. Gastric enteral nutrition cannot be started until gastric emptying improves. If it seems that gastric enteral nutrition would be unacceptably delayed, a more distal enteral route should be secured, or parenteral nutrition should be started. Patients with new gastrostomies, whether placed percutaneously or via an open procedure, rarely have postoperative motility disturbances. It is common, however, to wait for 24 hours before the use of gastronomy feeding tubes.

SMALL AND LARGE INTESTINE

Postoperative ICU patients with manipulation, resection, or diversion of the bowel may have a transient ileus. Small bowel hypomotility, if present, resolves 6 to 8 hours after

surgery, and some absorptive capacity is present even without normal peristalsis.^{88,89} Large bowel hypomotility, if present, begins to resolve 24 hours postoperatively, heralded by the passage of flatus. Recognized postoperatively as abdominal distention on physical examination or a non-obstructed gas pattern on abdominal x-ray study, ileus usually resolves over 24 to 72 hours with conservative therapy including nasogastric suctioning. Refractory ileus in the absence of mechanical obstruction should suggest some unresolved inflammatory process. In the absence of such unresolved problems, ileus also can be improved with prokinetic agents. Neostigmine has been successful in decompressing acute colonic pseudo-obstruction.⁹⁰ The presence of enterotomy repairs, bowel anastomoses, or new ostomies should not be barriers to enteral nutrition with the return of bowel function.⁹¹

FISTULAS

Nutritional support in the presence of an enterocutaneous fistula is problematic because enteral nutrition can exacerbate fistula output. This output, particularly when high, can perpetuate or worsen malnutrition owing to the loss of nitrogen and also lead to significant losses of intravascular volume and total body water. With the exception of some colocolic fistulas, conservative therapy consists of bowel rest (nothing per mouth), parenteral nutrition, control of infection, correction of electrolyte disturbances, and local wound care.

PANCREATITIS

Acute pancreatitis is treated commonly in the surgical ICU. In mild acute pancreatitis, enteral nutrition has no effect on outcome and is recommended only in patients who cannot tolerate oral nutrition after 5 to 7 days.⁹² In severe acute pancreatitis, the therapeutic pendulum has swung from bowel rest and parenteral nutrition back toward early enteral nutrition. Although no differences in mortality rate have been shown in severe acute pancreatitis between groups treated with enteral nutrition and parenteral nutrition, the early enteral nutrition group has significant reductions in stress response, infections, surgical interventions, and length of stay.^{93,94} The theoretical benefit of feeding beyond the ligament of Treitz versus gastric feeding in patients with severe acute pancreatitis remains controversial in the available literature.

NUTRITION IN WOUND HEALING

Nutritional deficiencies can impede wound healing. Large open wounds are metabolically demanding and may be a source of substantial protein loss. Daily dietary goals of calorie and protein need to be increased accordingly. Deficiencies of vitamins and minerals (micronutrients) are infrequent, but should be suspected in malnourished (including unusual dietary habits) patients, elderly patients, and patients who have been receiving parenteral nutrition. Vitamin and mineral supplementation should accompany dietary calorie and protein in patients with deficiencies, but the benefit of pharmacologic doses of these micronutrients in the absence of deficiency is unproved. Vitamin A has been shown to antagonize the detrimental effects of corticosteroids on inflammation, epithelialization, and collagen synthesis. However, it does not lower infection rates

or ameliorate impaired wound contraction associated with corticosteroid therapy.^{95,96} Currently, vitamin A is not routinely used to treat patients with corticosteroid-induced immunosuppression because evidence for benefit in clinical practice is lacking. Vitamin C is needed for hydroxylation of lysine and proline in collagen formation (see earlier discussion). The benefit of vitamin C supplementation in patients receiving a normal diet is not validated. Zinc is an essential trace mineral for protein synthesis, cell division, and protein synthesis; however, its supplementation has not been shown to be beneficial in patients who are not zinc deficient.⁷⁵ Glucosamine is required for the synthesis of hyaluronic acid, an abundant component of the extracellular matrix, but also lacks clinical validation of benefit.

WOUND HEALING AND CARE

PHYSIOLOGY AND BIOLOGY OF WOUND HEALING

Many tissues in the body respond to injury by undergoing a reparative process, which can be described histologically, biochemically, chronologically, or functionally. There are many ways to label these processes, but a simple and useful paradigm includes inflammatory, proliferative, and remodeling phases.^{97,98} The process begins with hemostasis, inflammation, and generation of an extracellular matrix on which proliferating cells can attach. Wound healing is locally coordinated by cytokines and facilitated by systemically mobilized cellular elements and noncellular substrate. Ultimately, the normal healing process ends with collagen maturation. Collagen develops its tensile strength through intermolecular cross-linking of fibrils into larger and longer bundles. The collagen mass undergoes continual synthesis and degradation as weaker, randomly oriented collagen fibers are reorganized into stronger, linear, highly cross-linked bundles aligned toward mechanical stress placed on the wound. This remodeling process may last 6 to 12 months, with the tissue never fully recovering its original strength. In normal circumstances, these phases tend to be sequential with generous overlap between the end of one phase and the beginning of the next.
